We report on the observation of surface gap solitons found to exist at the interface between uniform and periodic dielectric media with defocusing nonlinearity. We demonstrate strong self-trapping at the edge of a LiNbO₃ waveguide array and the formation of staggered surface solitons with propagation constant inside the first photonic band gap. We study the crossover between linear repulsion and nonlinear attraction at the surface, revealing the mechanism of nonlinearity-mediated stabilization of the surface gap modes.

DOI: 10.1103/PhysRevLett.97.083901

Interfaces between different physical media can support a special class of localized waves known as surface waves. Surface waves attract great attention with their possible application in surface sensing and probing. In periodic systems, staggered surface waves are often referred to as Tamm states [1], first identified as localized electronic states at the edge of a truncated periodic potential. Direct observation of electronic surface waves in natural crystalline materials remains beyond practical reach, but successful efforts were made to demonstrate their existence in nanoengineered superlattices [2]. In optics, linear staggered surface modes or Tamm states have been demonstrated at surfaces separating periodic and homogeneous dielectric media [3].

The nonlinear response of materials makes possible the dynamic control of surface localization. This ability has generated great interest in the study of nonlinear surface waves in different fields of physics and most extensively in optics. A self-focusing optical nonlinearity enables the existence of localized waves at interfaces between homogeneous dielectric media [4–6] where no linear modes exist. However, such surface modes are typically associated with high power requirements, and are not possible at all if the nonlinear response is self-defocusing. The combination of periodicity and nonlinearity allows one to overcome both of these limitations due to the ability of periodic structures to dramatically modify beam diffraction. This leads to a wealth of different types of modes localized at and near the surface [7]. Furthermore, nonlinear surface states hold promise for optical switching applications utilizing the mechanism of low-power beam delocalization and higher power confinement at the surface.

Self-trapping of light near the boundary of a self-focusing photonic lattice was predicted recently [8] and demonstrated in experiment [9] through the formation of discrete surface solitons at the edge of a nonlinear waveguide array. In self-defocusing materials the existence of surface gap solitons at the interface between uniform and periodic media was also recently predicted theoretically [8,10]. In this case, light localization occurs inside the photonic band gap in the form of staggered surface modes [10]. This enables one to extend the analogy with the localized electronic Tamm states into the nonlinear regime, so the surface gap solitons can be termed as nonlinear Tamm states.

In this Letter we study experimentally self-action of a narrow beam propagating near the edge of a LiNbO₃ waveguide array with defocusing nonlinearity. For the first time to our knowledge, we observe the formation of surface gap solitons, or nonlinear Tamm states. While linear surface modes do not exist in this type of system, discrete light self-trapping is observed in the nonlinear regime above a certain threshold power when the propagation constant is shifted into the gap of the photonic transmission spectrum. By employing a simple nonlinear discrete model [11], we describe the crossover from discrete diffraction and surface repulsion in the linear regime, to the appearance of a purely nonlinear localized surface state at higher optical intensities. We discuss the physical mechanism of the nonlinearity-induced stabilization of the staggered surface modes.

In our experiments, we study nonlinear surface localization in a semi-infinite array of single-mode optical waveguides fabricated by a titanium in-diffusion process in a monocrystal x-cut lithium niobate wafer, similar to that recently used for the observation of discrete gap solitons [12,13]. The fabrication process, described in Ref. [13], results in a high-quality waveguide array with refractive index contrast Δn = 3 × 10⁻⁴, waveguide spacing d = 9.0 μm, sample length 50 mm, and a total of 100 wave-
guides. The inset in Fig. 1(b) shows schematically the geometry of the waveguide array. The LiNbO$_3$ sample exhibits a strong photovoltaic effect which leads to defocusing nonlinearity at visible wavelengths.

In the experimental setup an extraordinarily polarized probe beam from a cw Nd:YVO$_4$ laser ($\lambda = 532$ nm) is focused by a microscope objective ($\times 20$) to a full width at half maximum (FWHM) of 2.7 $\mu$m at the input face of the sample, and injected into the waveguide at the edge of the array. The propagated wave packet at the output of the sample is imaged onto a CCD camera. The FWHM of the individual waveguide mode is 6 $\mu$m and 3 $\mu$m in horizontal and vertical directions, respectively, allowing for a single-waveguide input coupling. The waveguide array is externally illuminated by a white-light source in order to control the nonlinear response time. As shown in Ref. [13] single site excitation provides an efficient method for excitation of gap solitons in periodic defocusing nonlinear materials, provided the refractive index contrast exceeds a certain threshold. In this case the periodic structure appears equivalent to a discrete system [13] and can be well described by a nonlinear discrete model.

At low laser power (0.1 $\mu$W), we observe two major effects. First, due to coupling between neighboring waveguides the probe beam experiences discrete diffraction and spreads out in the horizontal plane upon propagation. Second, the beam shifts dramatically to the right indicating a strong repulsive effect of the surface. Figure 1(a) shows the experimental image of the output intensity distribution and the corresponding transverse intensity profile. After linear propagation through the array the beam profile acquires a complex form, where the major lobe is centered approximately 42 lattice sites away from the input excitation point ($n = 0$ at the edge of the array) due to the surface repulsion. Figure 1(b) shows the corresponding optical intensity distribution inside the sample, calculated with the help of a simple analytical formula derived from a discrete model $a_n(z,k) = A_0 e^{i \phi} [J_n(2z\kappa) + J_{n+2}(2z\kappa)]$, where $a_n(z,k)$ is the discrete mode amplitude in the $n$th waveguide, $A_0$ is the initial field amplitude in the input waveguide $n = 0$, $z$ is the propagation distance, and $\kappa$ is the intersite coupling coefficient [8]. In Fig. 1(b) the discrete mode amplitudes have been multiplied by the continuous waveguide mode intensity profile, and the agreement with the experimental observation is found to be excellent. The coupling coefficient is estimated to be $\kappa = 0.46$ mm$^{-1}$, implying a total propagation of 23 coupling lengths.

Increasing the laser power leads to spatial beam self-action through the defocusing photovoltaic nonlinearity. The slow response of the nonlinearity allows us to monitor directly the transient temporal dynamics of self-trapping and soliton formation. Figures 1(c)–1(e) show the output beam intensity profile at times 920, 1050, and 1550 s, respectively, after the beam power is increased to $P = 0.5$ mW. The wave packet is seen first to contract and shift towards the edge of the array, indicating a nonlinearity-induced suppression of the surface repulsion [Fig. 1(c)]. Then partial self-trapping at the surface occurs, with a tail of intensity lobes extending into the periodic structure [Fig. 1(d)]. A series of zero intensity points between these lobes indicates the self-induced dynamic formation of a staggered phase structure which is clearly absent in Fig. 1(a). Eventually, a strongly localized surface gap soliton is formed [Fig. 1(e)]. The asymmetry of the photonic structure is reflected in the shape of the trapped beam which decays monotonically into the continuum while showing damped oscillations inside the array, resembling the structure of a truncated Bloch mode. The defocusing nonlinearity effectively decreases the contrast of the surface waveguide, causing the localized mode to broaden and penetrate substantially into the continuous medium.

In order to study in detail the crossover between linear diffraction and nonlinear self-localization, we measure the surface gap soliton formation time as a function of the probe beam power. As seen in Fig. 2 the formation time increases dramatically for decreasing input power until, below a certain critical power, no localized surface mode is observed. This so-called critical slowing down indicates the existence of a threshold power below which the non-

Figure 3(b) shows a two-dimensional intensity plot of the interference fringes, corresponding to an exact associated interference pattern. A half-period vertical shift [10]. The mode is confined from the continuum by total features of the two different localization mechanisms at play. The staggered phase structure inside the array and the constant phase in the continuum are signatures of the two different localization mechanisms at play [Fig. 3(b)]. The phase is seen to be constant in the continuous region. The staggered phase structure inside the periodic medium. The alternating phase of the self-localized mode decreases for increasing beam power, spanning about three lattice sites immediately above threshold [Fig. 2(a)], and approximately a single lattice site at higher power [Fig. 2(c)]. The decrease of the beam width is due to the fact that stronger beam self-action at higher power leads to a deeper surface defect, and hence more pronounced beam localization.

An essential and unique feature of the observed surface gap solitons is the staggered phase structure of the beam tail inside the periodic medium. The alternating phase of the field lobes reflects the fact that the propagation constant of the self-localized mode lies within the photonic band gap at the edge of the first Brillouin zone. To verify that this is indeed the case in the experiment, we interfere the output beam with a vertically inclined plane reference wave. If this is indeed the case in the experiment, we interfere the output beam with a vertically inclined plane reference wave. The mode is localized from the continuum by total internal reflection, while Bragg reflection is responsible for localization inside the periodic structure.

In order to gain a deeper insight into the physics of staggered surface soliton formation, we consider the system of coupled-mode equations [14] for the normalized mode amplitudes $E_0$ and $E_n (n = 1, 2, \ldots)$, assuming weak coupling between the neighboring waveguides,

$$i \frac{dE_0}{dz} + E_1 + \mathcal{F}(E_0)E_0 = 0,$$

$$i \frac{dE_n}{dz} + (E_{n+1} + E_{n-1}) + \mathcal{F}(E_n)E_n = 0,$$  \hspace{1cm} (1)

where $\mathcal{F}(E) = \gamma/(1 + |E|^2)$ ($\gamma > 0$ for defocusing nonlinearity) accounts for the saturable character of the photovoltaic nonlinearity [15] and allows for correct description of the observed effects. This treatment is complementary to Ref. [10] where pure Kerr nonlinearity was considered.

Looking for stationary solutions in the form $E_n(z) = \exp(i\beta z)\tilde{E}_n$, we obtain the linear spectrum of extended modes, $\beta = 2\cos k$ ($0 \leq k \leq \pi$). No localized surface mode exists in the linear regime, as this would require large index contrast between the waveguides and the continuum. However, the presence of defocusing nonlinearity in the model (1) can give rise to localized states. To find them we solve numerically the corresponding stationary equations by a multidimensional Newton-Raphson scheme. Since we are interested in surface localized modes, we look for states with maxima near the surface which decay quickly away from the edge of the array. This approach is similar to the earlier studied cases of Kerr nonlinearity [8,10] and agrees qualitatively with the analysis of the continuous model [10].

Figure 4(a) shows the surface mode calculated by use of the discrete nonlinear model (1) and multiplied by the
waveguide mode-field profiles. Using the discrete model (1) provides reasonable agreement with the experimental data. An example of such a comparison is shown in Fig. 4(b) for the width of the localized surface state calculated numerically (solid curve) and measured experimentally (diamonds) as a function of the beam power. Vertical dashed line marks the threshold power ($P_{th} = 0.042$ mW).

In conclusion, we have shown theoretically and demonstrated experimentally that gap solitons can be stabilized near the surface of a periodic medium with self-defocusing nonlinearity in the form of staggered surface modes, providing experimental evidence of a nonlinear analog of surface Tamm states in optics.
