Abstract—Wireless power transfer (WPT) has emerged as an attractive solution to power future wireless communication networks. In this paper, we consider WPT using power beacons (PBs) for a millimeter wave (mmWave) wireless ad hoc network. Using stochastic geometry, we derive the moment generating function (MGF) and the nth cumulant of the aggregate received power from PBs at a reference receiver in closed-form. The MGF allows the complementary cumulative distribution function (CCDF) of the aggregate received power from PBs to be numerically evaluated. We also compare different closed-form distributions which can be used to approximate the CCDF of the aggregate received power. Our results show that the lognormal distribution provides the best CCDF approximation compared to other distributions considered in the literature. The results also show that under practical setups, it is feasible to power users in a mmWave ad hoc network using PBs.

I. INTRODUCTION

Wireless power transfer (WPT) is regarded as an attractive solution for future wireless networks [1]. Compared to energy harvesting from the ambient environment (e.g., using solar or ambient radio frequency (RF) energy harvesting), it has the advantage of being always available and controllable. There are currently two major approaches to WPT: (i) simultaneous information and power transfer (SWIPT) where information and power are extracted from the same transmitted signal [1] and (ii) power beacon (PB) based approach where dedicated low-cost transmitters, which do not require backhaul links like normal base stations, are deployed to charge users in their vicinity [2]. In this paper, we adopt the PB based approach in millimeter wave (mmWave) ad hoc networks.

MmWave transmission is a key enabler for future fifth generation (5G) wireless networks, since larger bandwidths are available at mmWave frequencies (> 6 GHz) compared to conventional microwave frequencies (< 6 GHz). MmWave systems have the following two distinctive features which have been recently characterized very well both experimentally [3] and analytically using stochastic geometry [4–7]: (i) propagation environment is more susceptible to blockage causing differences in the line of sight (LOS) and non light of sight (NLOS) path-loss and fading characteristics and the signal to drop out after a certain range and (ii) use of larger antenna arrays (possible due to smaller wavelength) for beamforming at the transmitter and receiver (RX). MmWave transmission is potentially a good combination with WPT, since both technologies operate over short distances and narrow beams in mmWave systems can focus the transmitted power [8].

In WPT systems, the aggregate received power (which determines the harvested power) plays a key role in the system performance. For instance, (i) in SWIPT systems, a common assumption is that the energy constrained node has a large battery to store the received power and, therefore, it transmits with a constant transmit power which is proportional to the aggregate received power [9,10], (ii) in PB systems, the complementary cumulative distribution function (CCDF) of the aggregate received power plays a key role in determining the power outage probability [2,11,12], and (iii) in low power applications, statistical information such as the mean and variance of the aggregate received power can potentially be used to develop efficient sleep and transmission protocols [1,13]. Thus, it is crucial to accurately characterize the aggregate received power. In this regard, the moment generating function (MGF) of the aggregate received power, which opens the door for application of powerful toolsets from stochastic geometry, has been numerically evaluated in microwave cellular and device-to-device networks with ambient RF energy harvesting [14,15], mmWave SWIPT systems [6,7] and microwave PB systems [11]. To the best of our knowledge, a closed-form expression for the MGF of the aggregate received power in mmWave PB systems, incorporating the key propagation characteristics of mmWave transmission, is not available in the literature.

In this paper, we consider a mmWave wireless ad hoc network where PBs are deployed. Using stochastic geometry, we characterize the aggregate received power at a reference RX. The novel contributions of this paper are:

- We derive the closed-form expressions for the MGF and the nth cumulant of the aggregate received power at the reference RX, taking a mmWave three-state propagation model and multi-slope path-loss model into account. The MGF allows the CCDF of the aggregate received power from PBs to be numerically evaluated.
- We test the accuracy of well known closed-form distributions to model the aggregate received power. Our results show that the lognormal distribution provides the best CCDF approximation, compared to other distributions

commonly considered in the literature.

- We investigate the feasibility of PBs to power users in a mmWave ad hoc network. Our results show that under practical setups, for PB deployment density between $10 - 100$ per km$^2$, the required PB transmitted power to achieve an average harvested power of 15 dBm is between $1.5 - 40$ W, which is practical and safe for human exposure.

II. SYSTEM MODEL

We consider a two-dimensional mmWave wireless ad hoc network, where PBs are deployed to charge users. The PBs are located outdoors and their locations form a homogeneous Poisson point process (PPP) $\phi$ with density $\lambda$. Throughout the paper, we use $X_i$ to denote both the random location as well as the $i$th PB itself. The PBs have access to a dedicated power supply (e.g., a battery or power grid) and transmit with constant power $P$ using beamforming. The PB transmissions set up an energy field over the wireless ad hoc network region and users harvest power from the aggregate PB received signal [16]. We assume that the PBs randomly and independently choose a direction to point their main beams. Given a sufficient density of the PBs, this simple strategy ensures that the aggregate received power from PBs at different locations in the network is roughly on the same order. Similarly, the users point their main beam in a randomly chosen direction. This avoids the need for channel estimation and accurate beam alignment. In this paper, without loss of generality, we focus on the characterization of the aggregate received power from PBs at an outdoor reference RX, $Y_0$, located at the origin.

**MmWave Blockage Model:** For outdoor mmWave transmissions, each link between the $i$th PB and the reference RX is susceptible to building blockages due to their high diffraction and penetration characteristics [4]. In this work, we adopt the state-of-the-art three-state blockage model [5], where each link can be in one of the following three states: (i) the link is in LOS state if no blockage exists, (ii) the link is in NLOS state if blockage exists and (iii) the link is in outage (OUT) state if the link is too weak to be established.

Assuming that the link between the $i$th PB and the RX has a Euclidean length of $r_i = ||X_i - Y_0||$, the probabilities $p_{\text{LOS}}(\cdot)$, $p_{\text{NLOS}}(\cdot)$ and $p_{\text{OUT}}(\cdot)$ of it being in LOS, NLOS and OUT states, respectively, are

$$p_{\text{LOS}}(r_i) = u(r_i - r_{\text{max}});$$
$$p_{\text{NLOS}}(r_i) = u(r_i - r_{\text{min}}) - u(r_i - r_{\text{max}});$$
$$p_{\text{OUT}}(r_i) = 1 - u(r_i - r_{\text{min}}),$$

where $u(\cdot)$ denotes the unit step function, $r_{\text{min}}$ is the radius of the LOS region and $r_{\text{max}}$ is the exclusion radius of the OUT region. The values of $r_{\text{min}}$ and $r_{\text{max}}$ depend on the propagation scenario and the carrier frequency. Typical values used in this work are summarized in Table II.

**MmWave Channel Model:** Measurements have shown that mmWave links experience different channel conditions under LOS, NLOS and OUT states [3]. Hence, in this work, we adopt a path-loss plus fading channel model as follows.

We assume that a link in LOS state experiences Nakagami-$m$ fading, while a link in NLOS state experiences Rayleigh fading. For the path-loss, we modify and adapt a multi-slope path-loss model and define the path-loss between the $i$th PB and the reference RX with a distance of $r_i$ as follows

$$l(r_i) = \begin{cases} 1, & 0 \leq r_i < 1 \\ r_i^{-\alpha_L}, & 1 \leq r_i < r_{\text{min}} \\ \beta r_i^{-\alpha_N}, & r_{\text{min}} \leq r_i < r_{\text{max}} \\ \infty, & r_{\text{max}} \leq r_i \end{cases},$$

where the first condition is added to ensure a bounded path-loss model, $\alpha_L$ denotes the path-loss exponent for the link in LOS state and subscript L denotes LOS, $\alpha_N$ denotes the path-loss exponent for the link in NLOS state (2 $\leq \alpha_L \leq \alpha_N$) and subscript N denotes NLOS, the path-loss of the link in OUT state is assumed to be infinite [5] and the continuity in the multi-slope path-loss model is maintained by introducing the constant $\beta = r_{\text{max}}^{-\alpha_L} - \alpha_N$ [17]. We also define $\delta_L = \frac{\alpha_L}{\alpha_N}$ and $\delta_N = \frac{\alpha_N}{\alpha_L}$ for convenience in presenting the analytical results in Section III.

**Beamforming Model:** We assume that antenna arrays are used for beamforming at both the PBs and the reference RX. Following [4, 5], we approximate the actual antenna array pattern by a sectorized gain pattern which can be expressed as

$$G_a(\theta) = \begin{cases} G_{\text{max}}^a, & |\theta| \leq \frac{\delta_L}{\delta_N} \\ G_{\text{min}}^a, & \text{otherwise}, \end{cases}$$

where subscript $a = pb$ for PB and $a = r$ for reference RX, $G_{\text{max}}^a$ is the main lobe antenna gain, $G_{\text{min}}^a$ is the side lobe antenna gain, $\theta \in [-\pi, \pi]$ is the angle off the boresight direction and $\theta_a$ is the main lobe beam-width. Note this model can be easily related to specific array geometries, such as an $N$ element uniform planar or linear or circular array [18].

As stated earlier, the main beam at the PBs and RX are assumed to be randomly oriented with respect to each other and uniformly distributed in $[-\pi, \pi]$. Let $G_l$ be the effective antenna gain on the link from the $i$th PB to the reference RX. As a result of sectorization, $G_l$ is a discrete random variable with probability distribution as $G_l = G_k$ with probability $p_k$, $k \in \{1, 2, 3, 4\}$. The values of $G_k$ and $p_k$ are summarized in Table I.

**Power Transfer Model:** We assume that the reference RX is equipped with a typical rectifier-based power receiver to

<table>

</table>
harvest power from the aggregate PB received signal [16]. Practical rectifier-based power receivers have a power receiver activation threshold \( \epsilon \), i.e., the power receiver is only activated when the aggregate received power from all the PBs is greater than \( \epsilon \) [11]. We assume that once the power receiver is properly activated, then the harvested power is linearly proportional to the aggregate received power from the PBs and the constant of proportionality \( \eta \) is the power conversion efficiency.

III. AGGREGATE RECEIVED POWER FROM POWER BEACONS

In this section, we provide the mathematical formulation to characterize the aggregate received power at the reference RX from all PBs.

Since the power harvested from the noise is negligible, the instantaneous aggregate received power at the reference RX from all the PBs can be expressed as

\[
P_{agg} = P \sum_{X_i \in \Phi} G_i h_i I(r_i),
\]

where \( P \) is the PB transmitted power, \( G_i \) is the effective antenna gain between \( X_i \) and \( Y_0 \), \( h_i \) is the fading power gain between \( X_i \) and \( Y_0 \), which follows the gamma distribution (under the Nakagami-\( m \) fading assumption) if the link is in LOS state and exponential distribution (under the Rayleigh fading distribution) if the link is in NLOS state and \( I(r_i) \) is the path-loss function in (2).

Note that \( P_{agg} \) in (4) is a random variable because of the randomness in the antenna gain, mmWave channels and locations of PBs. We use stochastic geometry to find its CCDF and also its \( n \)th cumulant.

A. CCDF and MGF of the Aggregate Received Power from Power Beacons

The CCDF of the aggregate received power at the reference RX from all the PBs can be obtained by using the Gil-Pelaez inversion theorem [19]

\[
Pr(P_{agg} > z) = \frac{1}{2} + \frac{1}{\pi} \int_0^{\infty} \text{Im}[\mathcal{M}_{P_{agg}}(-j\omega) \exp(-j\omega z)] \frac{d\omega}{\omega},
\]

where \( \text{Pr}(\cdot) \) denotes the probability, \( \text{Im}[\cdot] \) denotes the imaginary part of a complex number, \( j = \sqrt{-1} \) is the imaginary unit, \( \mathcal{M}_{P_{agg}}(s) = \mathbb{E}[\exp(-sP_{agg})] \) is the MGF of \( P_{agg} \) and \( \mathbb{E}[\cdot] \) is the expectation operator.

The following proposition characterizes the exact MGF of \( P_{agg} \) in closed-form.

**Proposition 1:** The MGF of the aggregate received power at the reference RX from all the PBs in a mmWave ad hoc network, following the system model in Section II, is

\[
\mathcal{M}_{P_{agg}}(s) = \sum_{k=1}^{4} \exp(\pi \lambda r_{\min}^2 m_0 \frac{m}{m_0}) (\mathbb{E}[P_{agg}(s)])^k (\sum_{k=1}^{4} \frac{\gamma_i}{\Gamma(\gamma_i)} - \mathbb{E}[P_{agg}(s)]) + \frac{\pi \lambda}{2 + m_0} \frac{m}{m_0} \beta \sum_{k=1}^{4} \frac{\gamma_i}{\Gamma(\gamma_i)} (\mathbb{E}[P_{agg}(s)])^k (\sum_{k=1}^{4} \frac{\gamma_i}{\Gamma(\gamma_i)} - \mathbb{E}[P_{agg}(s)])
\]

where

\[
\Xi_1(r) = m_0^{m_0(r-\alpha) + sPG_k - \delta_l - m_0\alpha_1} \frac{\Gamma(1 + m)}{(2 + m_0\alpha_1)\Gamma(m)}
\]

\[
\Xi_2(r) = \frac{r^{\alpha_2} + sPG_k^\beta}{r^{\alpha_2} + sPG_k^\beta},
\]

\[
\Xi_3(r) = \frac{r^{\alpha_2} + sPG_k^\beta - \delta_l - 1}{r^{\alpha_2} + sPG_k^\beta} \frac{\Gamma(2 + \alpha_2)}{sPG_k^\beta}
\]

\[
\Xi_4(r) = \frac{r^{\alpha_2} + sPG_k^\beta - \delta_l - 1}{r^{\alpha_2} + sPG_k^\beta} \frac{\Gamma(2 + \alpha_2)}{sPG_k^\beta}
\]

Remark 1: To the best of our knowledge, Proposition 1 presents the result for the MGF of \( P_{agg} \) in closed-form for the first time in the literature. In addition, (6) substituted in (5) allows the CCDF to be numerically computed. Note that although the MGF in (6) is in closed-form, the CCDF in (5) cannot be expressed in closed-form due to complexity of the MGF which is inside the integration. However, it can be easily evaluated numerically using Mathematica.

B. \( n \)th Cumulant of the Aggregate Received Power from Power Beacons

The \( n \)th cumulant of the aggregate received power at the reference RX from all the PBs, \( \kappa_{P_{agg}}(n) \), can also be expressed in terms of the MGF of \( P_{agg} \) as [20]

\[
\kappa_{P_{agg}}(n) = (-1)^n \frac{\partial^n \ln \mathcal{M}_{P_{agg}}(s)}{\partial s^n} \Bigg|_{s=0},
\]

where \( \ln \) is the natural logarithm. The following proposition characterizes the \( n \)th cumulant of \( P_{agg} \) in closed-form.

**Proposition 2:** The \( n \)th cumulant of the aggregate received power at the reference RX from all the PBs in a mmWave ad hoc network, following the system model in Section II, is given by

\[
\kappa_{P_{agg}}(n) = \sum_{k=1}^{4} \left( \Psi_k^1(n) - \Psi_k^2(n) - \Psi_k^3(n) \right),
\]

where

\[
\Psi_k^1(n) = \pi \lambda \rho_{\min} \frac{\rho_{\max}}{m_0} \frac{\Gamma(1 + m)}{\Gamma(m)}
\]

\[
\Psi_k^2(n) = \frac{2\pi \lambda \rho_{\min} \rho_{\max} \ln \rho_{\min}}{\Gamma(m)(2 + m_0)} \frac{\rho_{\max}}{m_0},
\]

\[
\Psi_k^3(n) = \frac{2\pi \lambda \rho_{\min} \rho_{\max}}{2 - m_0},
\]

\[
\Psi_k^4(n) = \frac{2\pi \lambda \rho_{\min} \rho_{\max}}{2 - m_0},
\]

See Appendix B.
C. Closed-form Approximation of the CCDF of the Aggregate Received Power

Since the exact CCDF of the aggregate received power cannot be expressed in closed-form, we test various distributions which can be used to approximate the CCDF in this section. The distribution of $P_{\text{agg}}$ is approximated by the well-known closed-form distributions by second-order moment matching, i.e., by matching the mean and the variance of the two distributions, where the mean and the variance of $P_{\text{agg}}$ can be found from Proposition 2. First, we present the skewness and the kurtosis of $P_{\text{agg}}$, which are two important measures of a real-valued random variable.

Skewness and Kurtosis of $P_{\text{agg}}$:

The skewness and the kurtosis describe the shape of the probability distribution of $P_{\text{agg}}$ and are given by

$$\text{Skew}[P_{\text{agg}}] = \frac{\kappa_{P_{\text{agg}}} (3)}{\kappa_{P_{\text{agg}}} (2)^{1.5}},$$

$$\text{Kurt}[P_{\text{agg}}] = \frac{\kappa_{P_{\text{agg}}} (4)}{\kappa_{P_{\text{agg}}} (2)^2}. $$

The skewness shows whether a distribution is left or right tailed and the kurtosis measures the heaviness of the tail.

Gaussian Distribution: The CCDF of the Gaussian distribution is

$$\Pr(P_{\text{agg}} > z)_{\text{Gaussian}} = Q \left( \frac{z - \mu_{\text{Gaussian}}}{\sigma_{\text{Gaussian}}} \right),$$

where $Q(\cdot)$ is the Q-function, $\mu_{\text{Gaussian}}$ and $\sigma_{\text{Gaussian}}$ are the first and the second cumulant of $P_{\text{agg}}$, respectively, which can be calculated by (11).

Lognormal Distribution: The CCDF of the lognormal distribution is

$$\Pr(P_{\text{agg}} > z)_{\text{lognormal}} = Q \left( \frac{\ln z - \mu_{\text{lognormal}}}{\sigma_{\text{lognormal}}} \right),$$

where $\mu_{\text{lognormal}}$ and $\sigma_{\text{lognormal}}$ are the location parameter and the scale parameter given by

$$\mu_{\text{lognormal}} = \ln \left( \frac{\kappa_{P_{\text{agg}}} (1)}{\sqrt{1 + \kappa_{P_{\text{agg}}} (2) \kappa_{P_{\text{agg}}} (1)^2}} \right),$$

$$\sigma_{\text{lognormal}} = \sqrt{\ln \left( 1 + \frac{\kappa_{P_{\text{agg}}} (2)}{\kappa_{P_{\text{agg}}} (1)^2} \right)}. $$

Gamma Distribution: The CCDF of the Gamma distribution is

$$\Pr(P_{\text{agg}} > z)_{\text{gamma}} = 1 - \gamma \left( \frac{k_{\text{gamma}}}{\gamma_{\text{gamma}}^2} \right) \frac{\Gamma(k_{\text{gamma}})}{\Gamma(k_{\text{gamma}})},$$

where $\gamma(\cdot,\cdot)$ is the lower incomplete gamma function, $k_{\text{gamma}} = \frac{\kappa_{P_{\text{agg}}} (1)}{\kappa_{P_{\text{agg}}} (2)}$ and $\gamma_{\text{gamma}} = \frac{\kappa_{P_{\text{agg}}} (2)}{\kappa_{P_{\text{agg}}} (1)}$ are the shape parameter and scale parameter of gamma distribution, respectively.

### IV. Results

In this section, we present the analytical or numerical results and compare with the simulation results. The simulation results are generated by averaging over 10^5 Monte Carlo simulation runs. The values of the main parameters are summarized in Table II, which are chosen to be consistent with the literature in mmWave and WPT [1, 4]. Note that if the distance between the PB and the RX is more than $r_{\text{max}} = 200$ m, the mmWave link is in OUT state.

#### A. Distribution Approximation of the Aggregate Received Power

The skewness and the kurtosis of $P_{\text{agg}}$ versus the density of PB $\lambda$ are plotted in Fig. 1(a) and 1(b) respectively for different path-loss exponents of LOS link $\alpha_L = 2, 2.5$ and different Nakagami-$m$ fading parameters $m = 5, 10$. We can see that the curves are monotonic for the considered range of $\lambda$. Smaller $\alpha_L$ and larger $m$ lead to smaller skewness and kurtosis. As the density of PB increases, the gap between the different curves becomes smaller. The distribution of the aggregate received power is skewed to the right with a heavy tail, because both the skewness and the kurtosis of $P_{\text{agg}}$ are much greater than 0. Moreover, the skewness and the kurtosis of a Gaussian distributed random variable are 0. Hence, we can conclude that the aggregate received power under the considered system model does not converge to a Gaussian distribution (even for the very extreme case with a PB density of 0.1 per m^2).

Fig. 1(c) plots the exact and approximated CCDF of $P_{\text{agg}}$ for $\alpha_L = 2$ and $m = 5$. The simulation results assume the LOS links undergo Rician fading with $K = 10$ dB. The exact CCDF is plotted numerically using (5) and (6), while the approximated CCDFs are obtained using (17) for Gaussian distribution, (18) for lognormal distribution and (21) for gamma distribution. From the figure, we can see that the CCDF of $P_{\text{agg}}$ under Rician fading LOS links can be closely approximated by Nakagami-$m$ fading by adjusting the $m$ values. Gaussian distribution does not provide a good approximation, which agrees with our discussion above. Gamma distribution is found...
to provide a close approximation to the power distribution of homogeneous PPP network [21] and heterogeneous PPP network [22] with non-singular path-loss model, but it clearly does not provide a good fit under the mmWave system model. We have tested the CCDF approximations using inverse Gaussian distribution, exponential distribution, Suzuki distribution and inverse gamma distribution against the exact CCDF and Rician LOS fading simulation under different channel parameters as well. However, they perform poorly and the results are omitted here for the sake of brevity. Overall, our results show that lognormal distribution provides the best CCDF approximation of $P_{agg}$.

**B. Mean Aggregate Received Power**

Next, we investigate the impact of the channel parameters and the beamforming parameters on the mean aggregate received power $\bar{P}_{agg} = \kappa P_{agg}$ (1).

Fig. 1. Skewness, kurtosis and CCDF approximation of the aggregate received power with the radius of the LOS region being 100 m and the PB and RX beamforming parameter being $[-20\,\text{dB},\,0\,\text{dB},\,30^\circ]$ and $[10\,\text{dB},\,-10\,\text{dB},\,45^\circ]$ respectively.

Fig. 2 plots $P_{agg}$ against the density of PB for different path-loss exponents of LOS link $\alpha_L = 2, 2.5$ and different radius of the LOS region $r_{min} = 50\,\text{m}, 100\,\text{m}$. We can see that the simulation results match perfectly with the analytical results. The figure also shows that $P_{agg}$ increases with $\lambda$. With smaller $\alpha_L$ and larger $r_{min}$, $P_{agg}$ grows at a faster rate. When $\alpha_L = 2.5$, the traces of two different $r_{min}$ overlap. We can see that the benefit of increasing the radius of the LOS region is insignificant, when $\alpha_L$ is large.

Fig. 3 plots $\bar{P}_{agg}$ against the density of PB for different beamforming parameters for PB and RX with the radius of the LOS region being 100 m and the path-loss exponent being 2 and the Nakagami-$m$ fading parameter being 5 for LOS links.
respect to $\lambda$.

C. Feasibility of WPT via PBs

In this section, we examine the feasibility of WPT via PBs in a mmWave ad hoc network. In this regard, it is important to note that the electronic circuitry of a power receiver has an activation threshold that has a value typically between $-30$ dBm and $-20$ dBm [1]. In addition, the typical maintenance power for a smart phone is between $20$ mW and $30$ mW [23].

Fig. 4 plots the maximum transmitted power of PB to achieve an average harvested power of $15$ dBm ($= 31.62$ mW), which is the typical maintenance power for a smart phone and is much higher than the power sensitivity level, versus the density of PB by assuming a constant power conversion efficiency of $\eta = 0.5$. From the figure, we can see that for a fixed PB density the decrease in the LOS path-loss exponents brings a higher saving in the transmitted power needed than the increase in the radius of LOS region. From Fig. 4, the maximum transmitted power required at a PB density of 10 per km$^2$ is 39.12 W. If PB transmits with this maximum value, the power density at a distant of 1 m from the PB is $3.113$ W/m$^2$. This power density is smaller than 10 W/m$^2$, which is the permissible safety level of human exposure to RF electromagnetic fields based on IEEE Standard [16].

V. CONCLUSIONS

In this paper, the mmWave wireless ad hoc network where RX harvests energy from all PBs was considered. We first derived the MGF and the $n$th cumulant of the aggregate received power at the RX to study the CCDF of the aggregate received power. Furthermore, we compared the different closed-form distributions which can be used to approximate the characteristics of the aggregate received power. Our results showed that the lognormal distribution provided the best CCDF approximation compared to other distributions considered in the literature for microwave network. The results have also shown that application of mmWave PB is feasible under practical network setup.

APPENDIX A

PROOF OF PROPOSITION 1

Following the definition of MGF,

$$M_{P_{\text{agg}}}(s) = \mathbb{E}[\exp(-sP_{\text{agg}})] = \mathbb{E}[\exp(-sP \sum_{i \in \Phi} G_i h_i l(r_i))]$$

$$= \mathbb{E}[\exp(-sP \sum_{0 \leq r < 1} G_i h_i l(r_i))] \times \mathbb{E}[\exp(-sP \sum_{1 \leq r < r_{\text{max}}} G_i h_i l(r_i))] \times \mathbb{E}[\exp(-sP \sum_{r_{\text{max}} \leq r < r_{\text{trans}}} G_i h_i l(r_i))].$$

where $E_{h_i, G_i}$ represents the expectation with respect to $h_i$ and $G_i$. The first term $A_1$ is evaluated as follows.

$$A_1 = \exp \left( -\pi \lambda \left( 1 - E_{h_i, G_i} \mathbb{E}[\exp(-sPG_ih_i)] \right) \right)$$

$$= \exp \left( -\pi \lambda \mathbb{E}[s\nu_{\text{min}}^p G_i] \left( m + sr_{\text{min}}^{-\alpha} PG_i \right)^{-m} \right)$$

$$= \exp \left( -\pi \lambda \mathbb{E}[s\nu_{\text{min}}^p G_i] \left( m + sr_{\text{min}}^{-\alpha} PG_i \right)^{-m} \right).$$

(23)

where we use the fact that the link in LOS state experiences Nakagami-$m$ fading with $f_{h_i}(h_i) = \frac{m^m h_i^{2m-1} \exp(- mh_i^2)}{\Gamma(m)}$.

The second term $A_2$ is evaluated as follows.

$$A_2 = \exp \left( \pi \lambda \mathbb{E}[s\nu_{\text{min}}^p G_i] \left( m + sr_{\text{min}}^{-\alpha} PG_i \right)^{-m} \right)$$

$$- \pi \lambda \mathbb{E}[s\nu_{\text{min}}^p G_i] \left( m + sr_{\text{min}}^{-\alpha} PG_i \right)^{-m} p_k$$

$$= \exp \left( \pi \lambda \mathbb{E}[s\nu_{\text{min}}^p G_i] \left( m + sr_{\text{min}}^{-\alpha} PG_i \right)^{-m} \right)$$

$$- \pi \lambda \mathbb{E}[s\nu_{\text{min}}^p G_i] \left( m + sr_{\text{min}}^{-\alpha} PG_i \right)^{-m} p_k$$

$$+ \pi \lambda \mathbb{E}[s\nu_{\text{min}}^p G_i] \left( m + sr_{\text{min}}^{-\alpha} PG_i \right)^{-m} p_k$$

(24a)

$$+ \pi \lambda \mathbb{E}[s\nu_{\text{min}}^p G_i] \left( m + sr_{\text{min}}^{-\alpha} PG_i \right)^{-m} p_k$$

(24b)
where (24a) follows from changing variables and integration by parts and (24b) is obtained after taking the expectation over $h_1$, then $G_1$.

Similarly, the third term $A_3$ can be worked out by taking the expectation over $h_N$, which has a PDF as $f_{h_N}(h) = \exp(-h)$. The details are omitted for sake of brevity. Finally, the MGF expression in Proposition 1 is obtained by substituting $A_1$, $A_2$ and $A_3$ into (22).

APPENDIX B

PROOF OF PROPOSITION 2

We cannot obtain the $n$th cumulant of $P_{agg}$ by directly substituting (6) into (10), as the cumulant becomes incomputable at $s = 0$. Instead, we use the integration form of the MGF in (22) and substitute in (10) to obtain

$$
\kappa_{P_{agg}}(n) = (-1)^{n+1} \left( \frac{d^n}{ds^n} \left[ \sum_{\alpha=0}^{n} \int_{0}^{\pi} E_{h_1, G_1} \left[ 1 - \exp(-sPG_1h_1) \right] \alpha \pi drd\theta \right] \right)_{s=0}
$$

$$
\int_{-\pi}^{\pi} \int_{-1}^{1} E_{h_1, G_1} \left[ 1 - \exp(-sPG_1h_1r^{-\alpha}) \right] \alpha \pi drd\theta
$$

$$
\int_{-\pi}^{\pi} \int_{-1}^{1} E_{h_1, G_1} \left[ 1 - \exp(-sPG_1h_1\beta r^{-\alpha}) \right] \alpha \pi drd\theta
$$

where $A_1$ is the first term evaluated as follows.

$$
B_1 = \int_{-\pi}^{\pi} \int_{-1}^{1} E_{h_1, G_1} \left( \frac{d^n}{ds^n} \left[ 1 - \exp(-sPG_1h_1) \right] \alpha \pi drd\theta \right)_{s=0}
$$

$$
= \int_{-\pi}^{\pi} \int_{-1}^{1} E_{h_1, G_1} \left[ (-1)^{n+1} \left( PG_1h_1 \right)^n \right] \alpha \pi drd\theta
$$

$$
= (-1)^{n+1} \pi \alpha \sum_{\alpha=0}^{n} \int_{0}^{\pi} E_{h_1, G_1} \left[ G_1^n \right] \alpha \pi drd\theta
$$

$$
= (-1)^{n+1} \pi \alpha \sum_{\alpha=0}^{n} \int_{0}^{\pi} E_{h_1, G_1} \left[ G_1^n \right] \alpha \pi drd\theta
$$

Similarly, the terms $B_2$ and $B_3$ can be derived by following similar steps as above. Substituting $B_1$, $B_2$ and $B_3$ into (25) gives the $n$th cumulant expression in Proposition 2.
