ABSTRACT

We present an analysis of a deep (1σ = 13 mJy) cosmological 1.2 mm continuum map based on ASPECS, the ALMA Spectroscopic Survey in the Hubble Ultra Deep Field. In the 1 arcmin2 covered by ASPECS we detect nine sources at z > 2 within the survey area. This value is significantly lower than that found in millimeter selected samples with a higher flux density cutoff and similar frequencies. Most galaxies have specific star formation rates (SFRs) similar to that of main-sequence galaxies at the same epoch, and we find median values of stellar mass and SFRs of 4.0 × 10^10 M☉ and ~40 M☉ yr⁻¹, respectively. Using the dust emission as a tracer for the interstellar medium (ISM) mass, we derive depletion times that are typically longer than 300 Myr, and we find molecular gas fractions ranging from ~0.1 to 1.0. As noted by previous studies, these values are lower than those using CO-based ISM estimates by a factor of ~2. The 1 mm number counts (corrected for fidelity and completeness) are in agreement with previous studies that were typically restricted to brighter sources. With our individual detections only, we recover 55% ± 4% of the extragalactic background light (EBL) at 1.2 mm measured by the Planck satellite, and we recover 80% ± 7% of this EBL if we include the bright end of the number counts and additional detections from stacking. The stacked contribution is dominated by galaxies at z ~ 1–2, with stellar masses of (1–3) × 10^10 M☉. For the first time, we are able to characterize the population of galaxies that dominate the EBL at 1.2 mm.

Key words: galaxies: evolution – galaxies: ISM – galaxies: star formation – galaxies: statistics – instrumentation: interferometers – submillimeter: galaxies

1. INTRODUCTION

One of the most fundamental discoveries with regard to the cosmic evolution of galaxies has been the determination that a substantial fraction of the integrated extragalactic background light (EBL) arises at infrared to millimeter wavelengths: the cosmic infrared background (CIB). Quantitative observations of the CIB began with the Cosmic Background Explorer (COBE). At a low angular resolution (0.7°), COBE provided the...
first large-scale measurement of the spectral energy distribution (SED) of the EBL from the far-infrared to the (sub)millimeter (Puget et al. 1996; Fixsen et al. 1998). The CIB consists of the combined flux of all extragalactic sources and contains much information about the history and formation of galaxies and the large-scale structure of the universe. The observation that the cosmic density of star formation was an order of magnitude higher at cosmological redshifts, $z \sim 2-4$ (e.g., Lilly et al. 1996; Madau et al. 1996), opened the possibility that most of the CIB arose from dust-reprocessed UV light from distant galaxies. These studies used the Lyman dropout technique to identify normal galaxies at high redshift, being mostly insensitive to dust-obscured star formation. Later, sensitive maps obtained with submillimeter/millimeter bolometer arrays were thus able to directly detect and identify luminous dusty star-forming galaxies (DSFGs), which were soon found to contribute a fraction to the EBL at these wavelengths (e.g., Smail et al. 1997).

Since then, a number of groups have conducted (sub) millimeter surveys of the sky, currently yielding up to hundreds of sources in contiguous areas of the sky (e.g., Barger et al. 1998; Hughes et al. 1998; Bertoldi et al. 2000; Eales et al. 2000; Cowie et al. 2002; Scott et al. 2002; Voss et al. 2006; Bertoldi et al. 2007; Greve et al. 2008; Scott et al. 2008; Weiß et al. 2009; Austermann et al. 2010; Vieira et al. 2010; Aretxaga et al. 2011; Hatsukade et al. 2011; Scott et al. 2012; Mocanu et al. 2013). These blank-field bolometer (sub) millimeter surveys discovered a population of luminous DSFGs at high redshift that were not accounted for in optical studies. These galaxies—also called “submillimeter galaxies” (SMGs) due to the region of the electromagnetic spectrum in which they were first discovered—have been characterized as massive starburst galaxies with typical stellar and molecular gas masses of $\sim 10^{11} M_\odot$, typically located at $z = 1-3$ (e.g., Chapman et al. 2005) with a tail out to $z \sim 6$ (Riechers et al. 2013; Weiß et al. 2013), and most likely driven by relatively bright mergers (Engel et al. 2010). As such, these galaxies are found to be gas/dust rich, with gas fractions typically exceeding 0.2 (e.g., Daddi et al. 2010a; Tacconi et al. 2010; Magdis et al. 2012; Bothwell et al. 2013; Tacconi et al. 2013). Despite their large SFRs implied by the large IR luminosities ($>10^{12.0-12.5} L_\odot$) and significant abundance at high redshift, these galaxies (e.g., $S_{1.2 \, \text{mm}} > 2-3 \, \mu\text{Jy}$) were found to contribute only a minor fraction of the EBL at submillimeter wavelengths (Barger et al. 1999; Eales et al. 1999; Smail et al. 2002; Coppin et al. 2006; Knudsen et al. 2008; Weiß et al. 2009; Scott et al. 2012; Chen et al. 2013). Hence, questions about the properties of the population of galaxies that dominate this EBL remain.

To locate and characterize the population of faint DSFGs that make up most of the EBL at (sub)millimeter wavelengths, we must overcome several observational limitations. First, the poor resolution of (sub)millimeter bolometer maps taken with single-dish telescopes, typically with beam sizes between 10"-30", makes the identification of an optical counterpart difficult and thus limits the characterization of submillimeter sources. In addition, this affects the number counts, since the brightest sources are seen to split into multiple components in high-resolution (sub)millimeter images (Younger et al. 2007; Wang et al. 2011; Smolcic et al. 2012; Hodge et al. 2013; Karim et al. 2013; Miettinen et al. 2015). Second, the sensitivity of single-dish bolometer maps, typically down to 0.5-1.0 mJy, along with confusion at the faint levels, limits our view to the most luminous sources. An important approach to reach fainter galaxies has been the use of gravitational lensing enabled by massive galaxy clusters (e.g., Smail et al. 1997, 2002; Sheth et al. 2004; Knudsen et al. 2008; Johansson et al. 2012; Noble et al. 2012; Chen et al. 2013). However, these surveys suffer severely from cosmic variance, due to the small areas covered in the source plane, source confusion, and the need for accurate lens models and magnification maps. A parallel approach has been to perform stacking of the submillimeter emission using preselected samples of optical/infrared galaxies. This approach has successfully resolved significant amounts of the EBL at (sub) millimeter wavelengths, reaching down to sources with $S_{1.2 \, \text{mm}} > 0.1 \, \mu\text{Jy}$ (Webb et al. 2004; Knudsen et al. 2005; Greve et al. 2010; Decarli et al. 2014). The major limitation of this approach is that it yields average properties over a population of galaxies that must be assumed to have similar (sub)millimeter properties.

The advent of the Atacama Large Millimeter/submillimeter Array (ALMA) is opening up a new window for the study of the faint DSFG population. Its significantly higher angular resolution compared to single-dish telescopes ($<3''$) and the unparalleled sensitivity allow us to reach flux density levels in (sub)millimeter continuum maps even deeper than those achieved by studies of galaxy cluster fields or based on stacking analysis. Several recent studies have individually pinpointed (sub)millimeter sources down to 0.1 mJy in the 1 mm band (Hatsukade et al. 2013; Ono et al. 2014; Carniani et al. 2015; Oteo et al. 2016; Dunlop et al. 2016; Hatsukade et al. 2016). Some of these surveys have used clever approaches by taking advantage of archival data (Ono et al. 2014; Carniani et al. 2015; Fujimoto et al. 2016), including ALMA calibration fields (Oteo et al. 2016). Recently, Fujimoto et al. (2016) were able to reach down to a flux limit of 15 $\mu$Jy at 1.2 mm, providing the deepest measurements of the number counts to date, and allowing them to resolve most of the CIB into individual sources. Despite the substantial progress, the current studies are still affected significantly by cosmic variance and are not “blank field” in nature (as some of them target overdense fields). Most importantly, the lack of sufficiently deep complementary data has only permitted the characterization of a handful of sources (Hatsukade et al. 2015; Fujimoto et al. 2016; Yamaguchi et al. 2016).

Using ALMA in Cycle 2, we have conducted a deep ALMA Spectroscopic Survey (ASPECS) of a region of the Hubble Ultra Deep Field (HUDF), covering the full 3 and 1 mm bands. In this paper, we present the deepest millimeter continuum images obtained to date in a contiguous 1 arcmin’ area. This is Paper II in the ASPECS series. A full description of the survey and spectral line search is presented in Walter et al. (2016, hereafter Paper I). Measurements of the CO luminosity function and cosmic density of molecular gas are shown in Decarli et al. (2016a, hereafter Paper III). A detailed analysis of the CO brightest objects is presented in Decarli et al. (2016b, hereafter Paper IV). A search for [CII] line emission is shown in Aravena et al. (2016a, hereafter Paper V). This paper is organized as follows: In Section 2, we summarize the ALMA observations and multiwavelength ancillary data available, and we also present the obtained ALMA continuum maps at 1.2 and 3 mm. In Section 3, we present the detected sources and compute the fidelity and completeness of our extraction procedures in the 1.2 mm map. In Section 4, we derive the
number counts at 1.2 mm. In Section 5, we characterize the multiband properties of the individually detected sources, including their typical stellar masses, SFRs, and redshifts, and discuss whether our sources are starbursts or more quiescent star-forming galaxies. In Section 6, we conduct a stacking analysis to determine the average properties of the faintest population of galaxies, not detected individually by our survey. In Section 7, we investigate the interstellar medium (ISM) properties of the individually detected sources based on measurements of the ISM masses from the 1.2 mm fluxes. We estimate their gas masses, depletion timescales, and fractions. In Section 8, we determine the contribution of both our individually detected and stacked sources to measure the fraction of the EBL at 1.2 mm resolved by our observations. We discuss the properties of the galaxies that dominate the CIB. Finally, in Section 9, we summarize the main results of this paper. Throughout the paper, we assume a standard ΛCDM cosmology with $H_0 = 70$ km s$^{-1}$ Mpc$^{-1}$, $\Omega_{\Lambda} = 0.7$, and $\Omega_M = 0.3$.

## 2. OBSERVATIONS

### 2.1. ALMA Observations and Data Reduction

The ASPECS survey setup and data reduction steps are described in detail in Paper I. Here we repeat the most relevant information for the study presented here.

ALMA band 3 and band 6 observations were obtained during Cycle 2 as part of projects 2013.1.00146.S (PI: F. Walter) and 2013.1.00718.S (PI: M. Aravena). Observations in band 3 were conducted from 2014 July 01 to 2015 January 05, and observations in band 6 were conducted from 2014 December 12 to 2015 April 21 under good weather conditions.

Observations in band 3 were performed in a single pointing in spectral scan mode, using five frequency tunings to cover 84.2–114.9 GHz. Over this frequency range the ALMA half-power beam width (HPBW), which corresponds to a primary beam (PB) response of 0.5, varies between 61″ and 45″. Observations in band 6 were performed in a seven-point mosaic, using a hexagonal pattern (Figure 1): the central pointing overlaps the other six pointings by about half the ALMA PB, i.e., close to Nyquist sampling. We scanned band 6 using eight frequency tunings, covering 212.0–272.0 GHz. The ALMA PB in individual pointings ranges between 30″ and 23″.

Observations in bands 3 and 6 were taken with ALMA’s compact array configurations, C34-2 and C34-1, respectively. The observations used between 30 and 35 antennas in each band, resulting in synthesized beam sizes of $3″ \times 2″$ and $1″ \times 0″$ from the low- to high-frequency ends of bands 3 and 6, respectively.

Flux calibration was performed on planets or Jupiter’s moons, with passband and phase calibration determined from nearby quasars, and should be accurate within ±10%. Calibration and imaging were done using the Common Astronomy Software Application package (CASA). The calibrated visibilities were inverted using the CASA task CLEAN using natural weighting. To obtain continuum maps, we collapsed along the frequency axis in the uv-plane and inverted the visibilities using the CASA task CLEAN using natural weighting and mosaic mode. We use the Multi-frequency Imaging Synthesis (MFS) algorithm with the parameter nterms = 1, since performing mosaic imaging with nterms>1 has not yet been implemented in the CASA software. This implies assuming a first-order polynomial fit for point sources along the frequency axis, which is the best assumption for low signal-to-noise ratio (S/N) data (most sources with S/N < 10) as in this paper (see CASA cookbook and Rau & Cornwell 2011). We also tested the effect of using different frequency weightings in the visibility plane; however, no significant changes were seen in the final collapsed images.

In this process, we produced “clean” maps masking with tight boxes all the continuum sources previously detected in the “dirty” maps with significances above 5σ, and cleaning down to a 2.5σ threshold. Given the large bandwidth covered by our
sources per deg². This translates into one source per deg⁵. This level where it becomes important for stacking analyses. With detections is negligible in these deep ALMA maps, it is at the 1.2 mm map was performed beyond the HPBW of our mosaic, evaluated locally for each source. Source extraction in the detection, extracting sources down to 2.5σ, where σ is evaluated locally for each source. Source extraction in the 1.2 mm map was performed beyond the HPBW of our mosaic, out to PB = 0.3; however, most sources are detected within PB = 0.5, in the central region of the mosaic. Although we extract all sources down to 2.5σ, we consider as individual detections only sources above >3.5σ significance. This significance level cut corresponds to roughly 50%–60% fidelity of the sample (see Section 3.2). These sources are highlighted with boxes in Figures 1 and 2 and are listed in Table 1.

Nine sources are detected in the 1.2 mm map at a significance above 3.5σ. For reference, Table 1 also lists another seven sources with significances between 3.0σ and 3.5σ (our supplementary sample). Given the lower significance...
of these sources, we choose not to use them to study the multiwavelength properties of this population. Nevertheless, we can use them to constrain the number counts of faint sources, after correcting for fidelity and completeness. Only one source is detected in the 3 mm map at the >3.5σ significance level, corresponding to the brightest detection at 1.2 mm. For this reason, we only show the 1.2 mm detected sources in Figures 1–2.

We compute fluxes based on a two-dimensional Gaussian fit centered at the location of the SExtractor detection. In all but one case (discussed below) the sources are unresolved at the resolution and depth of the 1.2 mm observations. We therefore list the flux as the peak flux density value at the source position delivered by the fitting routine. These fitted values are in agreement with the actual pixel values at the position of the sources. We cannot discard the possibility that sources with low significances are indeed being resolved given the relatively small beam size. It is thus unclear what fraction of the flux is being unaccounted for in individual sources.

Only the brightest source in the map is marginally spatially resolved with a measured angular size of (0.52 ± 0.14)° × (0.43 ± 0.26)° (PA = 49°), and we record the integrated flux in Table 1. More details on this source’s properties are given in Paper IV. Since only one source is detected in the 3 mm map, in what follows we concentrate on characterizing the properties of the 1.2 mm sources.

3.2. Fidelity and Completeness

We quantify the occurrence of spurious sources in our 1.2 mm sample by applying the detection routine explained in the previous section to the inverted “negative” map. We thus compute the fidelity $P$ of our sample as

$$P(S_{1.2\ mm}) = 1 - \frac{N_{\neg}(S_{1.2\ mm})}{N_{\pos}(S_{1.2\ mm})},$$

where $N_{\neg}$ and $N_{\pos}$ are the number of negative and positive sources, respectively, detected in the map as a function of 1.2 mm flux density.

Figure 3 shows the fidelity and number of positive detections in our map as a function of 1.2 mm flux density. Not surprisingly, we find that the fidelity of our sample is a strong function of the 1.2 mm flux density. We reach 100% fidelity at 100 $\mu$Jy (7.8σ) and 50% fidelity at 40 $\mu$Jy (~3.0σ). This means that at the 3σ level, half of our sources are expected to be spurious, which motivates our choice of a 3.5σ cut for the main sample.

We parameterize the fidelity with 1.2 mm flux density as

$$P(S_{1.2\ mm}) = \frac{1}{2} \text{erf} \left( \frac{\log_{10}(S_{1.2\ mm}) - A}{B} \right) + 1.0,$$

where $A = \log_{10}(42)$ and $B = 1/4$, and $S_{1.2\ mm}$ is in units of $\mu$Jy. We use this parameterization to compute the fidelity level or reliability of our individual detections.

We compute the completeness of our observations by running Monte Carlo simulations on our continuum map. We ingest 10 artificial point-like sources with randomly generated flux levels (between 10 and 300 $\mu$Jy) in the ALMA map. We then run our source detection procedure to identify and compute the fraction of recovered sources (versus the input sources). Recovered artificial sources are matched with the input positions within a radius of 1", roughly the size of our synthesized beam. Similar to the findings of Fujimoto et al. (2016), the input and recovered flux densities agree well within

(6) Flux density at 1.2 mm, corrected for PB. (7) Primary beam correction at the location of the detection in the 1.2 mm mosaic. (8) Flux density at 3.0 mm of the ALMA 1.2 mm continuum detection; upper limits are given at the 1.2 mm detection.

* Sources ASPECS C1, C2, and C6 in this paper correspond to sources 3 mm.1, 3 mm.2, and 3 mm.5, respectively, in Paper IV.
Figure 3. Left: fidelity (top panel) and number of detections (bottom panel) as a function of 1.2 mm flux density of the ASPECS sample (noncumulative). The solid curve is a model for the fidelity. Our sample shows 100% fidelity at $S_{1.2\ mm} \sim 100 \ \mu$Jy and 50% fidelity at $\sim 40 \ \mu$Jy (3$\sigma$). Right: completeness of our 1.2 mm continuum sample detection as a function of 1.2 mm flux density. The solid curve shows a model for the completeness behavior as a function of 1.2 mm flux density. Our sample shows 100% completeness at $S_{1.2\ mm} \sim 300 \ \mu$Jy and 50% completeness at $\sim 40 \ \mu$Jy (3$\sigma$).

individual source uncertainties. We repeat this process 10 times, for a total of 100 artificial sources. Note that we do not inject all 100 sources in a single step since this would result in significant source blending in the ALMA image.

Figure 3 shows the resulting completeness as a function of extracted 1.2 mm flux density. We find that our sample is 100% complete at $S_{1.2\ mm} \sim 300 \ \mu$Jy (23$\sigma$) and 50% complete at $\sim 40 \ \mu$Jy (3$\sigma$). This indicates that at the 3$\sigma$ level, we recover only half of real input sources.

We parameterize the completeness with 1.2 mm flux density as

$$C(S_{1.2\ mm}) = \frac{1}{2} \operatorname{erf} \left( \frac{\log_{10}(S_{1.2\ mm}) - A'}{B'} \right) + 1.0 \quad (3)$$

where $A' = \log_{10}(35)$ and $B' = 0.45$, and $S_{1.2\ mm}$ is in units of $\mu$Jy. We use this parameterization to compute the completeness level of our individual detections.

4. NUMBER COUNTS

We use the sources detected in our ALMA HUDF map to compute the number counts at 1.2 mm. We compute the number counts ($N(S_i)$) in each flux density bin $S_i$ as

$$N(S_i) = \frac{1}{A} \sum_{j=1}^{X_i} P_j C_j \quad (4)$$

where $A$ is the effective area of our ALMA mosaic and $X_i$ is the number of sources in each particular bin $i$. The parameters $P_j$ and $C_j$ correspond to the fidelity and completeness at the flux bin $i$. Since we are limited by the modest number of detections, we compute the cumulative number counts rather than computing differential counts by summing up each $N(S_i)$ over all measurements $> S_i$. In addition, we extend our number count measurements down to significances of 3$\sigma$. While at this level there is substantial contamination and low detection rate, we can statistically correct the values for fidelity and completeness. As pointed out in the previous section, at the 3$\sigma$ level we reach 50% fidelity and 50% completeness in our sample detection. This implies that these effects cancel out when we compute the number counts. Thus, while we obtain correct number counts at the 3$\sigma$ level, the identification of real sources is correct only in half of the cases.

The uncertainties in the number counts are computed by including the Poissonian errors and flux uncertainties in each individual measurement. The uncertainties in each bin are dominated by the Poissonian errors on $X_i$; however, at the lowest significance levels the flux uncertainties start to have a significant contribution.

The cumulative number counts ($N(\geq S_i)$) are shown in Figure 4. The actual measurements are listed in Table 2. For comparison, we show number count measurements from the literature (Hatsukade et al. 2013; Karim et al. 2013; Ono et al. 2014; Carniani et al. 2015; Oteo et al. 2015; Simpson et al. 2015; Fujimoto et al. 2016). We scale the flux densities of the different studies as $S_{1.2\ mm} = 0.85 S_{1.1\ mm}$ and $S_{1.2\ mm} = 1.3 S_{1.3\ mm}$ (for consistency with Fujimoto et al. 2016).

Our ALMA HUDF observations appear to be in general agreement with these earlier measurements, in particular with the counts obtained by Carniani et al. (2015) and Oteo et al. (2016). However, our counts are lower by about a factor of 2 in the flux range $S_{1.2\ mm} = 0.06-0.4 \ mJy$ compared to other studies in the literature (Hatsukade et al. 2013; Ono et al. 2014; Fujimoto et al. 2016). These differences could be explained by the fact that these studies might be biased as they used pointed observations toward brighter sources in the field to derive the number counts (i.e., these studies are not unbiased blank-field surveys).
Another possibility is that cosmic variance does play an important role among the different analyses; e.g., the ECDFS, where the HUDF resides, is believed to be underdense of submillimeter sources above \( \sim 3 \) mJy (at 345 GHz) by a factor of \( \sim 2 \) (Weiß et al. 2009). As indicated by several studies, the ECDFS appears to be underdense in other galaxy populations as well, including \( BzK \) galaxies and X-ray and radio sources (e.g., Lehmer et al. 2005; Blanc et al. 2008). However, as already noted by Weiß et al. (2009), the underdensity appears to be seen only in the brightest sources, given the steep slope at fainter fluxes (see also Karim et al. 2013). Another possibility is that the differences in number counts between studies come from scatter induced by different analysis techniques and methods. This effect was seen to be dominant compared to statistical fluctuations in radio surveys (Condon 2007).

### 5. MULTIWAVELENGTH PROPERTIES OF THE ALMA 1.2 MM SOURCES

#### 5.1. Astrometric Offset

Using the identified millimeter/optical counterpart positions (see below), we measure a systematic astrometric offset of the \( HST \) positions of \( \approx 0\arcsec.3 \) to the north of the ALMA positions. To check the ALMA registration, we inspected the millimeter calibrators used, finding good astrometric solutions, accurate within \( 0\arcsec.01 \) with respect to the cataloged radio-based values. Based on the GOODS 2008 data release documentation\(^{30}\), it is clear that a consistent offset (0\arcsec.32) was applied to the GOODS-North astrometric solution but not to the GOODS-South data. Hence, we correct the \( HST \) positions by 0\arcsec.3 to match the ALMA millimeter registration throughout. This is consistent with results from a shallower ALMA millimeter continuum

survey of the full HUDF (Dunlop et al. 2016; Rujopakarn et al. 2016).

5.2. Identification and SED Fitting

Figure 5 shows the location of the 1.2 mm continuum sources with respect to the optical galaxies in the field. Our blank-field observations encompass a significant number of optical galaxies; however, this is in contrast with the small number of galaxies detected in the millimeter regime. Our sources do not appear to be clustered.

For each individual 1.2 mm continuum detection, we identify optical counterparts within a radius of 1″ from the millimeter position. We choose this search radius since it is well matched to the ALMA 1.2 mm synthesized beam (1.7 ″ × 0.9 ″). Figure 6 presents multiwavelength cutouts for individual detections. Seven of the continuum sources with significances >3.5σ have an obvious counterpart in the HST images, and five of these have an available spectroscopic redshift (see Table 3; Skelton et al. 2014). The other two millimeter detections, with lower significances in our sample (~3.5σ–3.6σ), do not show an obvious counterpart. Four out of seven sources with significances between 3.0σ and 3.5σ do not have an optical counterpart (Table 1), consistent with the fidelity level at this significance, and indicating that some or all of these are likely spurious millimeter detections. Another possibility would be that these are faint dusty galaxies at higher redshifts (as in HDF850.1; see Walter et al. 2012).

We fit the SED of the continuum-detected galaxies using the high-redshift extension of MAGPHYS (da Cunha et al. 2008, 2015). We use the available 26 broad- and medium-band filters in the optical and infrared regimes, from the U band to Spitzer IRAC 8 μm. We here also include the ALMA 1.2 mm data flux densities; however we note that the optical/infrared data have a much stronger weight given the tighter constraints in this part of the spectra. We do not include Herschel photometry in the fits since its angular resolution is very poor, being almost the size of our target field for some of the IR bands. The Herschel photometry is thus heavily blended.

For each individual galaxy, we perform SED fits to the photometry fixed at the best available redshift. MAGPHYS delivers estimates for the stellar masses, star formation rate (SFR), dust mass, and IR luminosity. Even though for most galaxies we do not have photometric constraints on the observed IR SED, MAGPHYS employs a physically motivated prescription to balance the energy output at different wavelengths. Thus, estimates on the IR luminosity and/or dust mass come from constraints on the dust-reprocessed UV light, which is well sampled by the UV-to-infrared photometry. For some galaxies with faint optical/near-infrared fluxes or with weak constraints in the photometry, MAGPHYS is able to output only some of the parameters with enough accuracy (e.g., stellar masses). However, all the optical counterparts of our millimeter-detected sample are sufficiently bright to yield good parameters derived by MAGPHYS. The properties derived for individual sources detected in our ALMA 1.2 mm continuum are shown in Table 3.

Figure 7 shows the distribution of stellar masses and SFRs of our ALMA 1.2 mm continuum sources. For comparison, we show the stellar masses and SFRs derived in the same way for field galaxies located within the field of view of our ALMA map (within PB = 0.4) and selected to be in a redshift range that matches the redshifts of our ALMA continuum sources. We limit the comparison sample to sources with $m_{850LP}$ and $m_{160W} ≤ 27.5$ mag AB, in order to ensure good SED fits and derived properties. We find that the faint DSFG population, as revealed by our ALMA 1.2 mm sources, has higher stellar masses and SFRs than the field galaxy population at similar redshifts.
redshifts, yet much lower values than those found in brighter DSFGs (i.e., SMGs). Our sources show a median stellar mass of $4.0 \times 10^{10} M_\odot$ and a median SFR of $40 M_\odot$ yr$^{-1}$, which are significantly lower than the typical values for SMGs, with stellar masses in the range $(0.8-3.0) \times 10^{11} M_\odot$ (e.g., Michałowski et al. 2010; Hainline et al. 2011; Michałowski et al. 2012; Simpson et al. 2014; da Cunha et al. 2015; Koprowski et al. 2016) and SFRs well above $100 M_\odot$ yr$^{-1}$ (e.g., Casey et al. 2014).

5.3. Redshift Distribution

Since most of the galaxies detected at $>3.5\sigma$ in our sample have available spectroscopic redshifts from the various surveys of the HUDF, we investigate the redshift distribution of our sample.

Figure 8 shows the redshift distribution for our ALMA continuum sources that have an optical counterpart compared with various millimeter-selected samples of bright DSFGs from the literature.
We find that all the 1.2 mm continuum sources detected above 3.5σ in our sample are located in the redshift range $z = 1–3$, and none are associated convincingly with a galaxy at $z > 3$. This excludes the source candidates without counterparts. While this may only reflect the low number statistics due to the small area of the sky covered, it also supports the idea that the population of galaxies discovered in our deep ALMA 1.2 mm continuum map significantly differs from the population of DSFGs found in shallower but wider (sub)millimeter surveys. The DSFG samples from the literature are found to have median redshifts ranging from $\sim z = 2.1$ to $z \sim 3.1$, with a possible tail extending out to $z \sim 6$ (Chapman et al. 2005; Smolcic et al. 2012; Yun et al. 2012; Riechers et al. 2013; Weiß et al. 2013; Simpson et al. 2014; Miettinen et al. 2015; Dunlop et al. 2016; Strandet et al. 2016). We find that our faint ALMA millimeter-selected galaxies, however, have a median redshift $z = 1.7 \pm 0.4$. The uncertainty here corresponds to the scatter in the redshifts. This median redshift is significantly lower than the typical redshift of bright DSFGs, irrespective of the nature the DSFG samples (lensed or unlensed) or the selection wavelength (870 μm or 1.2 mm). Statistically, this would not be significantly affected if the two sources without counterparts were located at $z > 2$ given the small scatter in the redshift distribution.

While the SMG and fainter millimeter source populations are obviously different as reflected by the significantly lower 1.2 mm fluxes, this is the first time that we are able to evaluate the redshift distribution of the faintest 1.2 mm emitters in a contiguous blank field (below $S_{1.2 \text{ mm}} = 0.5$ mJy). Other studies reaching down to the faint millimeter flux regime are mostly based on archival data of different individual fields where the faint millimeter emitters are not the main targets (e.g., Carniani et al. 2015; Oteo et al. 2016; Fujimoto et al. 2016) or do not have the excellent deep multiwavelength coverage of the HUDF in order to address this issue.

The decline in the median redshift with decreasing flux density for millimeter-selected sources was recently predicted by phenomenological models of galaxy evolution (Béthermin et al. 2015). Even though the prediction does not assess the redshifts for populations with 1.2 mm flux densities below 0.2 mJy, already at this flux level they find a median redshift of $\sim 2$ compared to the much higher $z \sim 3$ predicted for brighter...

(10) ISM mass obtained from the 1.2 mm flux and the calibrations from Scoville et al. (2014).

Figure 7. Distribution of stellar masses and SFRs (obtained from SED fitting) for the galaxies detected in our ALMA 1.2 mm continuum map. For comparison, the distribution of field galaxies in the relevant redshift range is shown.

SMGs selected at 1.2 mm. By extrapolating their prediction down to a flux density cut of ~35 μJy (our 3σ cut), we find an expected median redshift of ~1.5. This value is in good agreement with our measurements and supports the fact that the redshift distribution of millimeter-selected galaxies is affected by the flux density cut.

5.4. Starburst versus Main Sequence

An important result from multiwavelength surveys in the past decade has been the determination that typical star-forming galaxies form a tight linear relationship in the SFR–M_{stars} plane out to z ~ 3 (e.g., Brinchman et al. 2004; Daddi et al. 2007; Elbaz et al. 2007; Noeske et al. 2007; Pannella et al. 2009; Karim et al. 2011; Rodighiero et al. 2011; Whitaker et al. 2012). Sources that lie close to this star formation relationship have been termed main-sequence galaxies. Galaxies lying above this sequence are called starbursts, as they have excess star formation activity with respect to most galaxies in the main sequence for the same stellar mass, or higher specific star formation rates (sSFRs). This sequence has been observed to evolve with redshift, with higher SFRs for a given stellar mass at increasing redshifts (Whitaker et al. 2012), and it has also been claimed to flatten at the high stellar mass end (Whitaker et al. 2012, 2014; Lee et al. 2015; Pannella et al. 2015).

Figure 8. Redshift distribution for (sub)millimeter-selected galaxies. The y-axis shows the number of galaxies in each bin, normalized to the total number of galaxies in each sample. The black solid line shows the redshift distribution of our ALMA HUDF 1.2 mm detections (>3σ). The gray and green solid lines show the redshift distribution for the 1.2/1.4 mm selected samples of SMGs in the COSMOS (Miettinen et al. 2015) and SPT surveys (Weiß et al. 2013), respectively. The dashed orange and blue lines show the 850/870 μm selected SMGs from Chapman et al. (2005) and from the ECDFS (Simpson et al. 2014).
for the left and right panels, respectively. We thus conclude that our faint ALMA 1.2 mm continuum sources are main-sequence galaxies at $z \sim 1$–3.

Recently, Hatsukade et al. (2015) studied the properties of four 1.3 mm detected sources with fluxes $S_{1.3\text{ mm}} > 0.2$ mJy (at least two times brighter than our sources). They find that these four galaxies are in the main sequence, with redshifts $z = 1.3$–1.6. However, those sources were selected in fields where these faint millimeter emitters were not the primary target. Most of these continuum sources lie in a dense environment at $z \sim 1.3$, and it is thus unclear how representative their redshift and properties are of the field population.

All the sources shown in Figure 9 lie within the uniform sensitivity region of our 1.2 mm mosaic, within PB = 0.4. However, there are a few of them that were not detected in the 1.2 mm continuum even though they have similar SFRs and stellar masses to the detected sources. This could partly be attributed to uncertainties in the SED fitting procedure or to the fact that some galaxies would be located at the very edges of our mosaic. However, it is possible that the nondetection of these sources could also be due to differences in the individual physical properties of these sources. For instance, galaxies with lower dust temperatures or masses would tend to produce lower fluxes at 1.2 mm, or they could just be dust poor. In Section 6 we address this issue using stacking analysis.

### 6. STACKING ANALYSIS

We use the stacking analysis to investigate the nature of the fainter galaxy population not detected at the achieved sensitivity limit of our ALMA 1.2 mm mosaic. To perform the stacking, we extract smaller images, $9'' \times 9''$ in size, from the final clean ALMA 1.2 mm continuum mosaic, centered at the position of sources that were selected from an independent galaxy catalog (see below). Subimages of the same size are simultaneously extracted from the PB sensitivity mosaic map. All these subimages are then combined together, to construct a weighted average using the PB sensitivity map as the weight. The noise in this average image is then obtained from an annulus around the central position with an initial and final radius of 4 and 12 pixels, respectively (1 pixel = $0.3''$). A summary of the stacking analysis results is shown in Figure 10 and listed in Table 4.

#### 6.1. Nature of Undetected Galaxies

Using stacking, we first investigate the emission from galaxies individually undetected at the 3.5σ level in the ALMA 1.2 mm continuum map as a function of redshift. If these galaxies were to follow a similar redshift distribution to that of the detected galaxies, then we would expect on average that the galaxies in the $1 < z < 2$ range would have more 1.2 mm continuum emission than those in other redshift ranges. Figure 10 shows the stacked emission of galaxies in three different redshift ranges (samples $z_1$, $z_2$, and $z_3$; see Table 4). All samples have been selected to have $M_b > 10^9 M_{\odot}$ and $z < 4$, and sources that enter the stack were required to lie $3''5$ away from the location of the five most significant individual continuum detections to avoid contamination. The restriction to have a relatively high stellar mass is specifically to not down-weight the stack signal. To avoid including passive evolving galaxies with no star formation activity in the stacks, we only select galaxies that are located within and above the main sequence (see Figure 9), taking into account a conservative 0.5 dex of scatter in the main-sequence relationship. The main-sequence trends as a function of redshift are taken from Whitaker et al. (2014). Additionally, to limit our sample only to galaxies with good measured SED fits, we require that the sample galaxies have magnitudes brighter than 27.5 AB in the F850LP and F160W bands. Galaxies detected at the $>3.5\sigma$ level in the 1.2 mm continuum have been excluded from the stacked samples. Using this selection, we only detect 1.2 mm emission from galaxies at $1 < z < 2$ (the $z_2$ sample). In all the other redshift samples, we do not find significant emission and thus place 3σ limits on the 1.2 mm flux densities (see Table 4). This implies that most of the underlying millimeter emission that is not directly detected in our ALMA continuum map...
comes from galaxies located at similar redshifts to those of the individually detected galaxies, which have matching redshift distribution with a median $z = 1.65$.

To shed light on whether the most massive or star-forming galaxies could have underlying 1.2 mm emission, we stack on different galaxy samples split in stellar mass and SFR. We use three samples divided by stellar mass and three samples divided by SFR (see Table 4). We apply the same restrictions as for the redshift samples, including the limit in stellar mass, the requirement that the galaxies lie within and above the main sequence, and the magnitude limit in the optical/near-infrared bands. The galaxies used in these stacks are represented by blue symbols in Figure 9 (this figure does not show galaxies at $z < 1$ and $z > 3$).

Figure 10. Stacked 1.2 mm continuum on the location of galaxies selected as summarized in Table 4 (see also text): galaxies selected in the redshift, stellar mass, and SFR ranges are shown in the top, middle, and bottom panels, respectively. Sources individually detected in the 1.2 mm map at S/N > 3.5 are not included in the stacks. The images shown are $3\arcsec 6 \times 3\arcsec 6$ in size. Solid white and dashed black contours represent the positive and negative signal, respectively. Contours start at $\pm 2\sigma$ in steps of $\pm 1\sigma$. 

Aravena et al.
Figure 10 (middle and bottom panels) shows the results of this exercise. From the three stellar mass samples, only the samples m2 and m3 present a tentative detection of the stacked 1.2 mm emission. For sample m1, we place a 3σ upper limit. This indicates that less massive galaxies have fainter millimeter continuum emission. Note that the stacked detection for the m2 sample is offset from the center, the reason for this shift being unclear since we are excluding sources near the most significant 1.2 mm sources. It is possible that this shift is related to the low S/N of the signal.

By stacking in samples that were selected based on their UV-derived SFRs (derived from SED fitting), we find a clear detection for the s3 sample, which includes all galaxies with SFR$_{UV}$ > 30 $M_\odot$ yr$^{-1}$. This is consistent with the detection of emission in the mass-selected samples m2 and m3, which have concordantly high median UV-derived SFRs. Note that most of the galaxies individually detected at 1.2 mm comply with the s3 sample selection. Thus, the detection of stacked continuum signal in the s3 sample implies that the individually undetected galaxies are just below the detection threshold of our survey, showing on average lower millimeter emission than the individually detected galaxies. The reason for this could be due to uncertainties in the derived stellar masses and SFRs, as well as different physical properties such as lower dust content (lower dust masses).

In summary, we find that most of the millimeter continuum emission of undetected galaxies is produced by galaxies in the redshift range $z = 1$–2 (sample z2). When we make stacks on stellar mass, we obtain detections for the stellar mass ranges $10^{9.5}$–$10^{10} M_\odot$ and $10^{10}$–$10^{10.5} M_\odot$ (samples m2 and m3). These stellar mass bins have median UV-derived SFRs in the range of $\sim$3–$30 M_\odot$ yr$^{-1}$. When we explicitly consider galaxy samples with UV-derived SFRs, we only obtain a detection for galaxies with SFRs $>30 M_\odot$ yr$^{-1}$ (but not for the 10–30 $M_\odot$ yr$^{-1}$ bin). These stacked detections reach down to 1.2 mm continuum fluxes of $\sim$10 $\mu$Jy.

### 6.2. Stacking in the 3 mm Continuum

Since there is only one significant source in the 3 mm continuum map, we use the stacking analysis to measure the average 3 mm emission from all the sources that were detected at $>3.5\sigma$ in the 1.2 mm map. The result of this procedure is shown in Figure 11. Including all the 1.2 mm sources in the stack, we find an average flux density of $S_{3 mm,all} = 12 \pm 3 \mu$Jy. Masking the individually detected source in the 3 mm map, we find an average flux density of $S_{3 mm,masked} = 9 \pm 3 \mu$Jy. Using the same stacking procedure and adopting the same samples on the 1.2 mm map (i.e., stacking the 1.2 mm detected sources to obtain the average 1.2 mm flux), we find $S_{1.2 mm,all} = 195 \pm 11 \mu$Jy and $S_{1.2 mm,masked} = 125 \pm 12 \mu$Jy, respectively.

The ratio between these measurements can now be used to obtain an estimate of the dust emissivity index $\beta$. We use a single-component modified blackbody dust model in the optically thin regime of the form $S_\nu \propto (1 - e^{-\tau})B_\nu(T_d)$ (see

**Note:** Columns: (1) Sample name. (2) Selection imposed for this sample. In all cases, we excluded the individually detected sources with $>3.5\sigma$. We limited the samples to have $M_*>10^9 M_\odot$, to be located within PB = 0.4, and to lie 3$'$ away from the five most significant 1.2 mm continuum detections to avoid contamination. Additionally, in order to reject non-star-forming sources in our stacks (i.e., old passive evolving galaxies), we restricted the samples to reside above the main sequence including its intrinsic scatter at the relevant redshift range (i.e., sources above MS-0.5 dex), using the calibrations from Whitaker et al. (2014). Only sources with m$_{F850LP}$ and m$_{AB}$ < 27.5 mag AB were included, in order to retain sources with good SED fits. (3) Median redshift of the selected sample. (4) Median SFR obtained from the optical/near-infrared photometry with MAGPHYS. (5) Median stellar mass obtained from the optical/near-infrared photometry with MAGPHYS. (6) Number of objects that entered the stack. (7) Average flux density at 1.2 mm obtained from the stacking procedure.
Weiss et al. (2007), where $S_0$ is the observed flux density, $B_ν$ is the Planck function, and $T_d$ is the dust temperature. It can be shown that in the Rayleigh–Jeans (RJ) limit,

$$\beta = \frac{\log (S_0) / \log (S_d)}{\log (ν_1) / \log (ν_2)} - 2,$$

where $S(ν_1)$ and $S(ν_2)$ are the flux densities measured at frequencies $ν_1$ and $ν_2$, respectively. Note that at the observed frequencies it is valid to assume the optically thin and RJ approximations.

For the galaxy individually detected in the 1.2 and 3 mm maps (ASPECS C1), we find $β = 1.3 ± 0.2$. For the stack sample that includes all the sources, we find $β = 1.1 ± 0.3$. Similarly, for the masked sample we find $β = 0.9 ± 0.4$. This result suggests a significantly lower dust emissivity index for the faint population of DSFGs than what has been typically found in galaxies in the local universe and the Milky Way, and also at high redshift, with $β$ ranging from 1.5 to 2.0 (e.g., Chapin et al. 2009; Draine 2011; Dunne et al. 2011; Planck Collaboration et al. 2011). Note that given the relatively small beam size of the 1.2 mm observations, we could be missing flux that could contribute to a larger $β$ value. Similarly, the stacked signal detected at 3 mm is weak, and its detection is thus marginal. Both issues could thus be affecting this result. Another possible cause for this low $β$ value is the fact that we are tracing fluxes at wavelengths that could receive contribution from free–free emission. This would tend to increase the flux at 3 mm, resulting in larger $β$. Finally, it is worth mentioning that due to the higher cosmic microwave background temperature with redshift, we would expect to see an increase in the average $β$ value with increasing redshift. Larger samples of faint DSFGs are needed to provide better constraints on this subject.

7. ISM PROPERTIES
7.1. Gas Masses from Dust, and Caveats

A useful method to compute ISM masses in galaxies has been the use of the dust mass as a proxy for the ISM content (Leroy et al. 2011; Magdis et al. 2011; Magnelli et al. 2012; Scoville et al. 2014; Genzel et al. 2015). Recently, Scoville et al. (2014) argued that under reasonable assumptions about the dust properties, reliable ISM mass measurements can be made based on flux measurements made in the RJ tail of the dust. The method was calibrated using massive galaxies at low and high redshift and assuming a fixed gas-to-dust ratio, which is expected to be fairly constant for a relatively ample range in properties (see Scoville et al. 2014, for details), and assumes a fixed dust temperature of $T_d = 25$ K. Note that there is a weak dependence of this method on $T_d$, since we are probing the RJ part of the spectrum. Following Scoville et al. (2014), we compute the ISM mass in units of $10^{10} M_\odot$ as

$$M_{\text{ISM}} = 1.2(1 + z)^{-4.8} \left(\frac{ν_{\text{obs}}}{350}\right)^{-3.8} \frac{Γ_0}{Γ_{\text{RJ}}} S_d D^2_L,$$

where $D_L$ is the luminosity distance in Gpc at redshift $z$, and $S_ν$ is the measured flux density in mJy at the observing frequency $ν_{\text{obs}}$ (in GHz). $Γ_{\text{RJ}}$ is a correction factor that takes into account the deviation from the RJ limit as we approach higher redshifts. This factor depends on $z$, $T_d$, and $ν_{\text{obs}}$, and becomes $Γ_0 = 0.76$ at $z = 0$ for $ν_{\text{obs}} = 242$ GHz and $T_d = 25$ K. This method to compute ISM masses assumes a dust emissivity index $β = 1.8$, which we use throughout for consistency with other studies.

MAGPHYS also delivers an estimate of the dust mass ($M_d$) using the median of the dust mass posterior probability when fitting the available photometry. From this dust mass estimate, and under the assumption of a fixed gas-to-dust ratio ($δ_{\text{GDR}}$) and that the ISM is mostly molecular, one can obtain a measurement of the gas mass as $M_{\text{gas}} = δ_{\text{GDR}} M_d$. For local galaxies it has been found that typically $δ_{\text{GDR}} \sim 72$ (Sandstrom et al. 2013); however, metallicity-dependent variations are likely to play a significant role (e.g., Rémy-Ruyer et al. 2014).

For the typical stellar masses of our sources ($\sim 10^{10^{11}} M_\odot$) and assuming that local calibrations apply, we would expect metallicities close to the solar value, $12 + \log(O/H) \sim 9$ (Tremonti et al. 2004). However, since the metallicities are lower at high redshift, the typical stellar masses of our sample imply metallicities of $\sim 8.4$ at $z \sim 1.5$ (Yabe et al. 2014; Zahid et al. 2014). This metallicity value would translate into $δ_{\text{GDR}} \sim 200$ (Rémy-Ruyer et al. 2014). Hence, we adopt this value to convert the dust masses obtained with MAGPHYS into gas mass estimates.

Paper IV provides a detailed discussion of the different available methods to compute the gas masses, based on the CO measurements for four sources in the ASPECS field. From Table 3, we find that the gas masses obtained using MAGPHYS SED fitting are consistent with the ISM estimates from the Scoville et al. method for the assumed $δ_{\text{GDR}}$. Paper IV finds that the gas estimates following Scoville et al. and the MAGPHYS SED fitting methods underpredict the gas masses by a factor of $\sim 3$–$4$ compared to the CO-based estimates. There are several reasons that could explain this discrepancy, including (i) a combination of high excitation and low $α_{\text{CO}}$ values in the CO measurements, (ii) systematics in the calibration of the dust-based measurements, and (iii) different spatial distributions of dust and molecular gas within individual galaxies (see Paper IV for details). Another important issue is that the Scoville et al. (2014) calibration uses a fixed $δ_{\text{GDR}}$ value assuming solar metallicity. This assumption is reasonable for massive galaxies ($\sim 10^{11} M_\odot$) as applied in their study; however, it may potentially underestimate the gas masses for less massive, lower-metallicity galaxies, for which a higher $δ_{\text{GDR}}$ should be used.

Most importantly, perhaps, is the fact that the Scoville et al. (2014) calibration uses a gas-to-dust ratio fixed value for a solar metallicity. This assumption is reasonable for massive galaxies as applied in their study ($\sim 10^{11} M_\odot$); however, it will likely result in lower gas masses for less massive, lower-metallicity galaxies, for which a higher $δ_{\text{GDR}}$ should be used.

Despite these uncertainties, the dust-based estimates constitute the only means to provide a measurement of the gas masses in our 1.2 mm continuum-detected sources, given that most of them do not have CO line detections. Table 3 lists the gas masses obtained using both the Scoville et al. and the MAGPHYS SED fitting methods. In what follows we only use the ISM masses obtained with the Scoville et al. method as a measure of the total molecular gas mass, under the assumption that most of the ISM of high-redshift galaxies is in the form of molecular gas.

7.2. Gas Depletion Timescales and Fractions

Figure 12 shows the ISM mass (using the Scoville et al. method) versus SFR (derived using SED fitting) for the
ALMA sources have been computed using the 1.2 mm continuum fluxes following the recipes from Scoville et al. (2014). Literature values typically assume a CO-luminosity-to-gas-mass conversion factor of $0.8 \, M_\odot/(\text{K km s}^{-1} \text{pc}^2)^{-1}$ for local starburst galaxies and SMGs, and 3.6 or 4.6 (same units) for local spirals and main-sequence galaxies at high redshift. For the CO-based gas mass estimates in the three galaxies detected in CO line emission (see Paper IV), we use a conversion factor of 3.6 (same units). For clarity, the magenta lines connect the 1.2 mm continuum and CO-based gas mass estimates. The dashed and dotted lines denote the two sequences of starbursts and main-sequence galaxies defined in Daddi et al. (2010b), respectively.

For comparison, we also show the gas masses and SFRs of literature sources that have been detected in CO emission. To avoid uncertainties due to gas excitation, we only chose literature sources that have been detected in CO emission. We use a $^{12}$CO-to-gas-mass conversion factor $\alpha_{\text{CO}} = 0.8 \, \text{K km s}^{-1} \text{pc}^2$ for the samples of ultra-luminous IR galaxies (Solomon et al. 1997) and both un lensed (Frayer et al. 2008; Coppin et al. 2010; Carilli et al. 2011; Ivison et al. 2011, 2013; Riechers et al. 2011a, 2011b; Combes et al. 2012; Thomson et al. 2012; Walter et al. 2012; Bothwell et al. 2013; Hodge et al. 2013; De Breuck et al. 2014) and lensed DSFGs (Harris et al. 2010; Ivison et al. 2010; Swinbank et al. 2010; Lestrade et al. 2011; Decarli et al. 2012; Fu et al. 2012; Harris et al. 2012; Aravena et al. 2016b). For the samples of local spirals (Leroy et al. 2008) and main-sequence galaxies (Daddi et al. 2010a; Magdis et al. 2011; Magnelli et al. 2012), we use $\alpha_{\text{CO}} = 4.6$ and 3.6 K km s$^{-1}$ pc$^2$, respectively. For reference, we also show the available CO-based gas mass estimates for the three 1.2 mm continuum sources in our sample that were detected in CO line emission (C1, C2, and C6; Paper IV). For these, a conversion factor of 3.6 K km s$^{-1}$ pc$^2$ has been used.

Our galaxies seem to span a significant range in ISM masses and SFRs. Two of our ALMA 1.2 mm sources appear to be aligned with the sequence formed by the local spirals and main-sequence galaxies at $z = 1$–2 defined by the dashed line (Daddi et al. 2010b). This includes two of the CO-detected galaxies, which are also detected in continuum. In particular, the 1.2 mm brightest galaxy in our sample falls into the group of main-sequence galaxies, supporting the identification of this galaxy as main sequence based on SFR–$M_\text{gas}$. Only one galaxy, the third brightest in our continuum sample, is clearly located in the starburst regime. Four other sources appear to lie in between the trends of starburst or main-sequence galaxies. We remark that the gas mass values derived from the 1.2 mm fluxes could be underestimated, as discussed in the previous section. This would thus imply that these four sources in our sample could belong to the trend of main-sequence galaxies.

We note that the fact that the starburst and main-sequence galaxy trends in this SFR–$M_\text{gas}$ plane appear to be well separated from each other, with virtually no source lying in between, partly relies on the use of fixed $\alpha_{\text{CO}}$ factors for each particular sample. While in several cases the $\alpha_{\text{CO}}$ conversion factor has been measured directly for the literature sources, we caution that the use of a binary set of values for this parameter may artificially lead to different star formation laws for starbursts and main-sequence galaxies (Ivison et al. 2011).

The $\alpha_{\text{CO}}$ factor depends on several parameters, including metallicity, gas temperature, and velocity dispersion, and should depend on individual galaxy properties such as the gas or SFR surface density (see Casey et al. 2014). Furthermore, the bimodality might be in part caused by the preselection of individual sources for CO follow-up, which biases the range of properties covered by targeted current observations. However, it should be pointed out that this separation is already seen when comparing the direct observables $L_{\text{CO}}$ and $L_{\text{IR}}$ (e.g., Daddi et al. 2010a; Genzel et al. 2010; Aravena et al. 2016b).

Figure 13 shows the implied gas depletion timescales ($t_{\text{dep}}$) and gas fractions ($f_{\text{gas}}$) as a function of redshift for our ALMA 1.2 mm continuum sources, compared to recent measurements of main-sequence galaxies at $z = 0.5$–3.0 (Geach et al. 2011; Saintonge et al. 2013; Tacconi et al. 2013). Observations of massive main-sequence galaxies ($M_\text{gas} > 10^{10} M_\odot$) have shown evidence for a significant dependency of $t_{\text{dep}}$ out to $z = 3$ (Saintonge et al. 2013; Tacconi et al. 2013; Genzel et al. 2015), consistent with models of galaxy formation. These studies show a dependency of $t_{\text{dep}}$ with redshift with the form $(1 + z)^\gamma$, with $\gamma$ varying between $-1.5$ and $-1.0$ (Tacconi et al. 2013), as shown in Figure 13. Recent studies, however, show that $\gamma$ can be as low as $-0.3$ (Genzel et al. 2015). Similarly, as shown in the bottom panel of Figure 13, $f_{\text{gas}}$ shows a significant dependency with redshift, which appears to flatten at $z > 3$ (Saintonge et al. 2013).

The gas depletion timescales for our faint 1.2 mm sources are consistent with the ranges found for main-sequence galaxies at similar redshifts. Only one galaxy has a $t_{\text{dep}}$ value that puts it clearly in the range occupied by starburst galaxies. However, our galaxies present gas fractions ranging from 0.06 to 0.2 for the $z \sim 1.5$ sample, which is significantly lower than other main-sequence galaxies at similar redshifts. Only the higher-redshift galaxy in our sample, ASPECS C1 at $z = 2.5$, has a value of $f_{\text{gas}}$ comparable to literature sources at its redshift. This implies that while most of our galaxies have measured gas depletion timescales that agree with previous studies for main-sequence galaxies, they have gas fractions that are much lower than those found for the same comparison samples.

Several factors could affect the measured $t_{\text{dep}}$ and $f_{\text{gas}}$. This can partly be attributed to uncertainties in the derived parameters through SED fitting. However, we are using very deep multiwavelength photometry, and thus the derived SFRs...
and stellar masses should be as accurate as in previous studies. This is indicated by the fact that the ranges for the location of the main sequence at different redshifts in Figure 9 are consistent with those from the literature (Whitaker et al. 2014). Another possible explanation is that the gas masses computed using the 1.2 mm flux densities are being underestimated. A factor of \( \sim 2-3 \) higher gas masses, as those derived from CO (see Paper IV), would place the measured gas fractions more in line with the expected values for main-sequence galaxies, while retaining high gas depletion timescales.

Additionally, our sample presents significant scatter in both plots. This scatter is unlikely caused by the possible underestimation of the gas masses, where we would expect a more systematic effect. In this case, our sources present a scatter that is consistent with the typical one found in other samples studied in CO emission (Geach et al. 2011; Saintonge et al. 2013; Tacconi et al. 2013). Because of this scatter and the relatively narrow redshift range covered by our ALMA detections, it is hard to establish any evolutionary trend with the available data.

8. CONTRIBUTION TO THE EBL AT 1.2 MM

8.1. Integrated Intensity and Fraction of the EBL

We use the number counts at 1.2 mm derived in Section 4 to calculate the contribution to the EBL at 1.2 mm. Although our source number counts are derived from a small area of the sky, they are based on a deep contiguous blank field.

To calculate the contribution to the cosmic background at 1.2 mm from our measurements, we directly integrate the number counts, corrected for fidelity and completeness, down to the faintest flux bin \( (S_{\text{1.2 mm}} \sim 37 \mu\text{Jy}) \). We obtain an integrated intensity of \( 7.8 \pm 0.4 \text{ Jy deg}^{-2} \). The uncertainty is derived from the sum of the uncertainties of the individual detections, corrected for fidelity and completeness. However, our number counts do not extend to fluxes above 0.6 mJy. To estimate the contribution of the bright end of the number counts, which are not traced by our survey, we use the results from Karim et al. (2013) and Oteo et al. (2016). While the Karim et al. (2013) results are measured at 870 \( \mu\text{m} \), we chose them since they are based on ALMA high-resolution observations and thus take better into account the multiplicity and false detection rate issues seen in single-dish telescope bolometer surveys. It is a well-known result from their study that bolometer surveys overpredict the number counts at the bright end (above \( S_{870 \mu\text{m}} > 6 \text{ mJy} \)). We convert their counts from 870 \( \mu\text{m} \) to 1.2 mm using \( S_{\text{1.2 mm}} = 0.4 \times S_{870 \mu\text{m}} \) and add their contribution by integrating the values in their Table 1. Similarly, we use the Oteo et al. (2016) results to account for the contribution to the integrated intensity between 1.2 mm fluxes of 0.6 and 1.9 mJy, which are not covered by either the Karim et al. or our measurements. To fill this gap, we extrapolate the Oteo et al. number counts (in log–log space). By adding up the contribution of all galaxies starting at our faintest flux bin, we find an integrated intensity of \( 8.6 \pm 0.7 \text{ Jy deg}^{-2} \).

To compute the CIB at the frequency of our observations, we make use of the latest values derived by Planck Collaboration et al. (2014). By interpolating the Planck measurements (see their Table 10) over the frequency range of our observations (212–272 GHz), we find an EBL at \( \sim 242 \text{ GHz} \) of \( 14.2 \pm 0.6 \text{ Jy deg}^{-2} \) (Figure 14). From this, we find that our number counts recover \( \sim 60 \pm 6\% \) of the EBL at 242 GHz. Note that the EBL value at 242 GHz measured by Planck is much more precise than that measured by COBE 20 yr ago, and we thus adopt this value.

In order to account for the missing contribution to the EBL, we use stacking analysis. We follow the procedure explained in Section 6. We select the same samples (see Table 4), but in this case we limit them to exclude all sources with a detection at the \( >3\sigma \) level in order to be consistent with the faintest flux level taken into account to derive the number counts. In all cases, the samples differ by at most two sources with respect to those listed in Table 4. Hence, we find similar results to those...
presented in Section 6. We thus use the fluxes and number of objects for the m2 and m3 samples to compute the integrated intensity from the faintest, undetected sources. We find an extra contribution of 2.8 ± 0.5 Jy deg⁻², or ~20% ± 4% of the EBL at 242 GHz (Figure 14). Combining this with our measurement from the number counts implies a total intensity of 11.4 ± 0.8 Jy deg⁻², which makes up 80% ± 7% (~77%–84%) of the EBL at 242 GHz measured by Planck (Figure 14).

8.2. Nature of the Sources That Make Up the EBL

A critical result from this study corresponds to the properties of the galaxies that contribute to the EBL at 242 GHz. Based on our number count measurements only, we obtained an integrated intensity of 7.8 ± 0.4 Jy deg⁻². This makes up 55% ± 4% of the EBL measured by Planck at 242 GHz, implying that the population of galaxies that dominates this background is composed by the galaxies individually resolved by our ASPECS survey. From Section 5, we determined that slightly less massive galaxies by our ALMA HUDF would likely come from less massive galaxies 242 GHz can be resolved by individually detected galaxies, by the COBE wavelength. However, the contribution of the Planck satellite has much better precision and is within the uncertainties of the COBE measurement. As such, the recent measurements from the literature imply very high resolved fractions of the EBL, in some cases even exceeding the Planck measurements at 242 GHz. We note that the EBL is a grand average of the extragalactic emission over the whole sky. Therefore, measurements covering ~1 arcmin⁻² or less of the sky, aiming to resolve the sources contributing to this background, will be most likely highly affected by cosmic variance. If the observations were pointed to an overdense region of the sky, this will translate into a higher number of sources and higher resolved fraction of the EBL. In particular, Figure 4 shows that for the flux range 0.08–0.6 mJy our cumulative number counts are significantly lower, by a factor of ~2, than the values derived by Hatsukade et al. (2013) and Fujimoto et al. (2016) yet more consistent with the counts derived by Oteo et al. (2016) and Carniani et al. (2015). This substantial difference in the number counts, possibly due to the small areas covered but also to the fact that these studies are not “blank field,” would explain the differences in the measured intensities and resolved fraction of the EBL between different studies. As shown in Scoville et al. (2013), small-scale source density variations can cover significant fractions of the sky (see their Figures 9–11). As explained in Section 4, the number count differences might also be due to different methods and analysis tools used. In any case, measurements on larger fields will help to elucidate the effect of small-scale structure on the EBL at millimeter wavelengths.

9. CONCLUSIONS/SUMMARY

Using ALMA in Cycle 2, we have conducted a millimeter spectroscopic survey by scanning the full 3 and 1.2 mm bands over a region in the HUDF. The collapsed cubes constitute the deepest continuum images ever obtained over a 1 arcmin² contiguous area of the sky. The main results of our continuum measurements can be summarized as follows:

1. We detect nine sources with significances >3.5σ at 1.2 mm and only one source at 3 mm. From these detections, we measure the 1.2 mm number counts over the flux density range $S_{1.2}$ mm = 0.036–0.57 mJy. Our number counts are similar to previous measurements, with differences within a factor of ~2.

2. We measure the properties of the individually detected galaxies at S/N >3.5. We find that there is a large spread in stellar masses and SFRs, with median values of $4 \times 10^{10}$ $M_\odot$ and $\sim 40$ $M_\odot$ yr⁻¹, much lower than found in brighter SMGs. We find that these faint DSFGs are systematically located at lower redshifts than millimeter-selected SMGs, with a median redshift of $z = 1.7$. All galaxies are consistent with being close to the main sequence at their respective redshift.

3. We use stacking analysis to estimate the average emission from samples of galaxies selected by redshift, stellar mass, and SFRs. We only find detections in samples selected in the redshift range $1 < z < 2$, as well as in the

31 Over this flux range, the Fujimoto et al. results fully rely on the observations analyzed by Hatsukade et al. Thus, these studies measure effectively the same number of sources.
stellar mass ranges \( \log (M_*/M_\odot) = 9.5-10.0 \) and \( (M_*/M_\odot) = 10.0-10.5 \), with typical SFRs of \( 3-10 M_\odot \) yr\(^{-1} \). This suggests that the rest of the emission, not individually detected in our survey, comes from galaxies less massive, with lower SFRs, but at a similar redshift to those of the detected sources.

4. We use the 1.2 mm flux as a proxy for the ISM masses in our individually detected galaxies. We find that most of our sources are located in the star-forming trend occupied by main-sequence galaxies and local spirals, implying relatively large gas time depletion timescales, typically above 300 Myr, and a large spread in the molecular gas fractions ranging from 0.1 to 1.0. We compare these results with ISM mass estimates using CO as a tracer in Paper IV.

5. Our individual detections alone are able to resolve 55% ± 4% of the EBL at 242 GHz measured by the Planck satellite. By adding up the integrated intensity from our number counts, to the contribution from the bright end of the number counts—mostly composed by SMGs—and the contribution of faint galaxies detected using stacking, we are able to resolve between 77%–84% of the CIB at 242 GHz. The typical properties of the population that makes up most of the EBL at these frequencies correspond to those of the galaxies described in this work.

We thank the anonymous referee for her/his positive feedback and useful comments. M.A. acknowledges partial support from FONDECYT through grant 1140099. F.W., I.R.S., and R.J.I. acknowledge support through ERC grants COSMIC–DAWN, DUSTYGAL, and COSMICISM, respectively. F.E.B. and L.I. acknowledge Conicyt grants Basal-CATA PFB–06/2007 and Anilo ACT1417. F.E.B. also acknowledges support from FONDECYT Regular 1141218 (FEB) and the Ministry of Economy, Development, and Tourism’s Millennium Science Initiative through grant IC120009, awarded to the Millennium Institute of Astrophysics (MAS). E.D.C. gratefully acknowledges the Australian Research Council as the recipient of a Future Fellowship (project FT150100079). D.R. acknowledges support from the National Science Foundation under grant number AST-1614213 to Cornell University. I.R.S. also acknowledges support from STFC (ST/L00075X/1) and a Royal Society/ Wolfson Merit award. Support for R.D. and B.M. was provided by the DFG priority program 1573 “The Physics of the Interstellar Medium.” A.K. and F.B. acknowledge support by the Collaborative Research Council 956, sub-project A1, funded by the Deutsche Forschungsgemeinschaft (DFG). P.I. acknowledges Conicyt grants Basal-CATA PFB–06/2007 and Anilo ACT1417. R.J.A. was supported by FONDECYT grant number 1151408. This paper makes use of the following ALMA data: ADS/IAO.ALMA#2013.1.00146.S and ADS/IAO.ALMA#2013.1.00718.S. ALMA is a partnership of ESO (representing its member states), NSF (USA), and NINS (Japan), together with NRC (Canada), NSC and ASIAA (Taiwan), and KASI (Republic of Korea), in cooperation with the Republic of Chile. The Joint ALMA Observatory is operated by ESO, AUI/ NRAO, and NAOJ. The 3 mm part of the ALMA project was supported by the German ARC.

Figure 14. Extragalactic infrared background SED compared to the amount of intensity resolved by our ALMA HUDF observations. The shaded blue area represents the cosmic IR background revealed by the Planck satellite observations and the range of uncertainties in the measured data. Note that the uncertainty is so small that the shaded area resembles a thick line. The yellow circle shows the integrated intensity of our ASPECS observations at 242 GHz (11.4 Jy deg\(^{-2}\)), including both the measurement based on the number counts and the stacking analysis. The open circle shows the intensity recovered by the number count measurements only (without stacking). The green triangle shows the measurement made by Fujimoto et al. (2016) based on archival 1.2 mm data.
