We investigate theoretically the magnetoplasmon (cyclotron) resonance in a hybrid system consisting of spatially separated two-dimensional layers of electron and dipolar exciton gases coupled via Coulomb forces. We study the dynamics of this system under the action of a weak alternating external electromagnetic field in the presence of a uniform magnetic field, perpendicular to the layers. We reveal that the electromagnetic power absorption exhibits a double-resonance spectrum. We show that the first resonance is associated with the conventional well-studied magnetoplasmon excitations of the electron gas and it has a standard Lorentzian shape, whereas the second resonance is a peculiarity attributed to the Bose-condensed exciton gas. Further, we explicitly demonstrate that the spectrum of the system exhibits an asymmetric Fano-type profile, where the excitonic peak is extremely narrow in comparison with the magnetoplasmon one. We show that the shape of the resonance and the position of the peaks depend on the magnitude of the applied magnetic field, exciton-condensate density, and exciton-impurity scattering time. In particular, the Fano profile turns into a Lorentzian shape with decreasing exciton-impurity scattering time and the position of the plasmon-associated resonance is mainly sensitive and determined by the magnetic field strength, whereas the exciton-condensate peak position is determined by the exciton-condensate density. It opens the experimental possibility to determine the latter quantity in cyclotron resonance experiments.

Introduction. Hybrid Bose-Fermi systems represent a test bed for studying many-body phenomena and are a promising platform for future applications [1]. In cold atomic gases, recent research has been concentrated on studies devoted to the Feshbach resonance phenomena [2–5] and aimed at tuning the strength of the two-particle interaction between atoms, leading to new types of phase transitions [6,7]. In the solid state, Bose-Fermi mixtures are usually studied employing exciton or exciton-polariton gases [8] which represent Bose-Einstein condensates [9,10] (BECs) interacting with either electrons and holes coexisting in the same layers or neighboring two-dimensional layers containing electronic gases (2DEG). In particular, it has been demonstrated that the interaction between a 2DEG and the indirect excitons can lead to the formation of a so-called excitonic supersolid phase [11,12].

One of the possible physical realizations of Bose-Fermi systems is a semiconductor heterostructure, where the bosonic subsystem is represented by excitons localized in a quantum well (QW) or double quantum well (DQW), and fermions are a 2DEG in a parallel QW. In the lateral (let it be $xy$) plane, both the excitons and electrons can propagate freely. Their motion, self-interaction, and exciton-electron interactions result in the possibility for each sort of particles to propagate along different paths which, in order, can interfere between each other. In the case of constructive interference, it is reasonable to assume that we can achieve enhancement phenomena and the emergence of resonant effects. Instead, destructive interference might result in the suppression of particle transport [13,14]. In this Rapid Communication we are aiming at checking this assumption. In particular, we are interested in the Fano resonance phenomenon which is known to be a general type of resonance and it can be observed in the case of path interferences [15]. The Fano resonance is conventionally characterized by a peculiar asymmetric profile of the spectral line. In particular, it usually consists of two peaks and one dip. One of the peaks lies in close proximity to the dip, manifesting the coexistence of resonant transmission and reflection in the system.

Theory of magnetoplasmon resonance. We consider a system which represents two parallel layers of electrons and excitons (see Fig. 1). Electrons occupy the QW and form a 2DEG. The excitons are considered to be rigid dipoles, having their dipole moment oriented perpendicular to the plane of the layers containing the DQW and moving freely as a whole within. We assume that the exciton’s internal degrees of freedom are not excited by the external applied electromagnetic (EM) field or temperature, thus we consider a zero-temperature case when the quantum effects manifest themselves most clearly. The uniform magnetic field is directed along the growth axis of the structure, thus it is oriented perpendicular to the electronic and excitonic layers. We will also assume that the magnetic field is weak and thus it cannot affect the exciton center-of-mass motion. In contrast, it can substantially affect the motion of electrons.

Such an external EM field, $\mathbf{E}(\mathbf{r},t) = (E_0,0,0)\exp(-i\omega t)$, with the electric field component lying in the plane of the QW, produces deviations of the electronic density from its equilibrium value, $\delta n(\mathbf{r},t) = n(\mathbf{r},t) - n_0$, where $\mathbf{r}$ is a vector coordinate in the QW plane, and $\mathbf{k}$ is the in-plane wave vector. In typical

\*vadimkovalev@isp.nsc.ru
with electrons, which we will show below. Gas density can be influenced by the field via an interaction between the Fourier components of the induced (plasmon) field by the electronic layer acts as an effective resonator amplifying the amplitude of the plasmon frequency at a given wave vector, then the comparison with the amplitude of the external field, where $\tau_e$ is the electron relaxation time [16]. Nevertheless, the exciton density in the excitonic BEC, $\delta N_{k\omega}$, can be estimated as $g_0 ≈ 4\pi e^2 d/\epsilon$, and $M$ is the exciton mass. In the long-wavelength limit, $k^2 eB/mc^2 ≪ 2g_0n_e$ elementary excitations represent the sound quanta, $\epsilon_k ≈ sk$, where $s = \sqrt{8\pi n_e/m}$ is their velocity.

Further, in order to find the response function of the condensate, we use the Gross-Pitaevskii equation

$$i \partial_t \Psi(r,t) = \left( \frac{k^2}{2M} - \mu + g_0|\Psi(r,t)|^2 \right) \Psi(r,t) + \Psi(r,t) \int d\mathbf{r}' V(\mathbf{r} - \mathbf{r}') \delta n(\mathbf{r}',t),$$

where the last term describes the electrostatic interaction of excitons with the fluctuating electron density. We will treat it here as a perturbation, within the linear response approach. The wave function of the condensed particles, $\Psi(\mathbf{r},t)$, can be split into the stationary uniform part and the perturbed contribution, $\Psi(\mathbf{r},t) = \sqrt{n_c} + \psi(\mathbf{r},t)$. Further, the response function of the condensate excitons, $P_{k\omega}$, can be defined as

$$\delta N_{k\omega} = P_{k\omega}V_k\delta n_{k\omega},$$

and $\delta N_{k\omega} = \sqrt{n_c}^2 - \psi(\mathbf{r},t)$ is a perturbation of the condensate particle density. Then, the linearization of (5) gives

$$P_{k\omega} = \frac{n_k k^2}{M} \left( \frac{\omega}{\omega+i\delta} \right)^2 - \frac{\epsilon_k^2}{\tau_e}.$$  

It should be noted that simple consideration described above disregards the processes of exciton scattering on impurities, developed in Refs. [17,18].

In our recent work [19], it has been demonstrated that the exciton-impurity scattering results in a finite value of the lifetime of the bogolons, $\tau_k = \tau_s - i\gamma_k$, where

$$\gamma_k = \frac{1}{\tau_s} (k\xi)^3,$$

under the assumption $k\xi ≪ 1$ (we neglect here broadening caused by the exciton-exciton scattering [20]). Here, $\tau_s$ is the exciton-impurity scattering time in a normal exciton gas state and $\xi = 1/2M\sigma$ is the healing length.

Thus, the response function, Eq. (7), should be modified according to the substitution $\delta \rightarrow \gamma_k$.

Combining Eq. (6) together with Eqs. (1)–(3) and defining the renormalized conductivity as $j_{k\omega} = \sigma_{k\omega}E_0$ yields

$$\sigma_{k\omega} = \frac{1}{\sigma_B} + i \frac{e^2}{\epsilon k} \left( \frac{U_k}{\epsilon k} + \frac{V_k}{\epsilon k} P_{k\omega} \right),$$

$$\sigma_B = \frac{1}{\epsilon k} \left( \omega_k + i \right)^2 - \omega_k^2 \epsilon_k \tau_e.$$  

where $\omega_k = eB/mc$ is the electron cyclotron frequency and $\sigma_0 = e^2 n_e \tau_e/m$ is the static Drude conductivity of the electron.
Results and discussion. Let us investigate the properties of the power absorption function. In the calculations we use the following parameters: \(d = 10^{-6} \text{ cm}, a = 10^{-5} \text{ cm}, k = 4.2 \times 10^4 \text{ cm}^{-1}\), and \(\sigma_0 = 3.2 \times 10^{-5} \text{ cm}^{-1}\).

Figure 3 demonstrates the power absorption spectrum of the system with the emergence of the Fano resonance. Increasing the velocity of the Bogoliubov excitations \(s\), we shift the Fano resonance in frequency. In particular, Figs. 3(a) to 3(c) correspond to the celebrated asymmetric Fano profiles, whereas Fig. 3(b) corresponds to the symmetric configuration. It should also be mentioned that the mutual disposition of the peaks and the dip of our asymmetric resonance is changed from Figs. 3(a) to 3(c).

Figure 4 shows the power absorption spectrum in the log scale for a fixed value of \(s = 6.9 \times 10^5 \text{ cm/s}\) [corresponding to Fig. 3(c)] and different values of the impurity-mediated scattering rates. The frequency range is restricted to the high-\(\omega\) region corresponding to the second peak in Fig. 3(c). It is clearly seen that with the increase of the excitonic impurity-mediated lifetime (which corresponds to the decrease of the influence of the impurity-assisted scattering), the resonant
peak becomes more Fano-like and we observe the emergence of a dip in the power absorption spectrum around $\omega \tau_e = 29$.

Figure 5 explains the dependence of the power absorption coefficient on the magnitude of the external applied magnetic field presented in units of $\omega_c \tau_e$. The increase of the magnetic field ($\omega_c \tau_e$) gives a similar effect as the increase of $s$ (see also Fig. 2). However, it should be noticed that the position of the magnetoplasmon resonance is determined by the magnetic field strength, whereas the Fano-type resonance coming from the exciton subsystem is determined by the Bogoliubov sound velocity $s$ (compare Figs. 3 and 5). The latter, in turn, is determined by the exciton-condensate density since $s \sim \sqrt{n_c}$. These dependencies can, for instance, be used to experimentally control the spectral properties of the system under consideration.

It is also important to mention that if it happens that the plasmon modes are strongly damped, then their dispersion branches turn into the electron-hole continuum. Thus, in order to observe the predicted effect, it is crucial that the following inequality holds, $s > v_F$, where $v_F$ is the Fermi velocity of the electron gas. This inequality can always be satisfied for typical exciton densities $10^{10}$–$10^{12}$ cm$^{-2}$ used in modern experimental DQW structures.

Conclusions. We have developed a model of magnetoplasmon resonance in a hybrid structure consisting of interacting electron and dipolar exciton gases. We show that the Coulomb interaction between them results in hybridization of the density waves of both the subsystems with the appearance of a different double-peak dispersion. We attribute the emergence of this hybrid mode to the cyclotron resonance effect. It has also been shown that the power absorption spectrum demonstrates several interesting features, in particular, the Fano-type shape of the resonance in relatively pure samples. We expect that these modes can be easily found experimentally by well-developed techniques, used in the study of plasmons in low-dimensional nanostructures.
