Two-dimensional van der Waals materials have rich and unique functional properties, but many are susceptible to corrosion under ambient conditions. Here we show that linear alkylamines \( n-C_\text{m}H_{2m+1}NH_2 \), with \( m = 4 \) through 11, are highly effective in protecting the optoelectronic properties of these materials, such as black phosphorus (BP) and transition-metal dichalcogenides (TMDs: WS\(_2\), TaS\(_2\), NbSe\(_2\)). As a representative example, \( n\)-hexylamine \( (m = 6) \) can be applied in the form of thin molecular monolayers on BP flakes with less than 2-nm thickness and can prolong BP’s lifetime from a few hours to several weeks and even months in ambient environments. Characteristics combined with our theoretical analysis show that the thin monolayers selectively sift out water molecules, forming a drying layer to achieve the passivation of the protected 2D materials. The monolayer coating is also stable in air, \( H_2 \) annealing, and organic solvents, but can be removed by certain organic acids.

**Results**

The coating process is divided into 2 steps: 1) The sample together with silicon substrate is put in the liquid \( n\)-hexylamine for 20 min under 130 °C. This step creates coating on sample, but minor cracks might exist. 2) To fix the cracks, the sample is then immersed in hexylamine vapor for another 20 min at 130 °C and then annealed in argon for 30 min under 200 °C after the surface molecular monolayer stabilizer | multilayer 2D materials | anticorrosion

Passivation of materials in air and water is foundational to our civilization (1). When we consider the robust ultrathin passivation of 2D materials (2–7), it should be even more essential because 1) the thickness of passivation layer on 3D materials like Si, Al, Cr, etc. stays 2 to 5 nm over a very long time, which is an insignificant fraction of the remaining unreacted bulk material. However, one cannot say this for thin 2D materials with their total thickness likely comparable to the native oxide passivation layers. Thus, the atomic details of passivation matter even more here. 2) An ultrathin, electronically insulating layer provides opportunity to engineer extremely thin vertical heterostructures, akin to the SiO\(_x\)/Si gate in metal-oxide-semiconductor field-effect transistors. For these reasons, it is becoming increasingly critical to facilitate passivation of 2D materials such as transition-metal dichalcogenides (TMDs), black phosphorus (BP), silicone, stanene (8–12), etc., which are susceptible to corrosion under ambient conditions with air, water, or even small amounts of acidic or basic contaminants (9, 10, 13–19).

Several passivation strategies have been developed for these layered materials including covering by more robust 2D materials such as graphene (20) and hexagonal boron nitride (21). However, many previous strategies suffer from processability issues and other drawbacks: Metal-oxide coatings are prone to cracking (14, 22); polymers [e.g., poly(ethylene oxide) (PMMA), polystyrene, Parylene, and perylene-3,4,9,10-tetracarbonyl dihydride] are readily attacked by organic solvents and offer limited durability (19, 23–26); self-assembled monolayers with silane-terminated octadecyltrichlorosilane are highly toxic (27). Here, we discovered a one-pot scalable process for passivating a large variety of 2D van der Waals materials. It involves coating a nanometer-thick monolayer of linear alkylamines onto the surface of 2D materials, which greatly increases the lifetime of these materials in ambient environments with moisture and can sustain even harsh aqueous and thermal conditions. First-principles simulations suggest that the alkylamine coating significantly slows down the permeation of \( O_2 \), which reacts with the 2D layered material to form an ultrathin oxide passivation layer, and completely blocks \( H_2O \) molecules and shuts down the cycles of oxidation–dissolution, leading to the extended lifetime for many different classes of 2D crystals.

Since BP is the most vulnerable to corrosion among the 2D van der Waals (vdW) materials studied in this work and creates the most challenges for processing, it is used here as an illustrative example of the alkylamine coating. As a representative example of linear alkylamines \( n-C_\text{m}H_{2m+1}NH_2 \), \( n\)-hexylamine \( (m = 6) \) coating onto BP is systematically investigated both theoretically and experimentally in its corrosion inhibition mechanism and behaviors.

**Significance**

A family of strong yet removable 1- to 2-nm-thick ultrathin monolayer is developed as a corrosion inhibitor for 2-dimensional materials that significantly prolong lifetime while protecting optoelectronic properties in both ambient and harsh chemical or thermal environments. This method is low in toxicity and can be applied to arbitrary substrate with no size limit.

is cleaned by hexane. The hexane cannot remove the hexylamine coating but only the surface contamination, as shown later. More detailed coating procedures are presented in SI Appendix, Fig. S1 (28–40). The optimization of coating parameters of n-hexylamine onto BP is shown in SI Appendix, Table S1.

Once mechanically exfoliated, the bare BP flakes are highly reactive and chemically unstable. After keeping a 3-nm-thick BP flake in ambient air (humidity ∼35%) for 2 d (the thickness is estimated using the method from ref. 9), only vague traces remain (Fig. 1A), even when care is taken to prevent light exposure, known to accelerate the damage. As shown in Fig. 1A, the 3 characteristic Raman peaks of BP at 361 cm−1 (A1g), 438 cm−1 (B2g), and 466 cm−1 (A2g) completely disappear after 2 d. The degradation of BP is further expedited when exposed to light, in line with previous reports (9) which showed that the lifetime of bare BP (defined as the time needed for the Raman intensity to drop to e−1 of its original) is τ ∼1 h when a 2.8-nm-thick sample is exposed to a photon flux of 1.8 × 105 W/cm2, and τ ∼10 min when exposed to a photon flux of 1.7 × 106 W/cm2.

In contrast, n-hexylamine protected BP (HA-BP hereafter), which is kept side-by-side with the unprotected one, exhibits robust BP characteristics for a much-extended period. The difference in optical contrast for HA-BP between 0 and 111 d is essentially indiscernible (Fig. 1B); 31% of the intensity of A2 was retained after 111 d. The photon fluence seen by HA-BP during Raman measurements in 111 d is equivalent to light exposure of 1.0 × 105 W/cm2 for ∼2 h in total. Since such photon exposure is already known to be substantial to cause the degradation of bare BP (ref. 9), we conclude that the lifetime of HA-BP can be extended even further if the sample has not been exposed to the laser beam of the Raman characterization.

The coating process involves the proton transfer of the hydroxylated BP to the −NH2 group of n-hexylamine based on the evidence below. First-principles simulations suggest that n-hexylamine forms a molecular monolayer as shown in Fig. 2A. The top layer of the BP surface is rapidly oxidized from the oxygen dissolved in liquid hexylamine, forming PO−OH, PO−O, or P=O surface groups. Experimental evidence supports a model where the acidic PO−OH groups on the BP surface and the terminal −NH2 groups of alkylamines undergo a Brønsted–Lowry acid–base reaction to form a layer of alkylammonium salts that coat the BP surface through a strong electrostatic interaction with the deprotonated PO−O− surface sites. Confirmation that the neutral −NH2 group in n-hexylamine becomes charged (i.e., −N+H3) came from X-ray photoelectron spectroscopy (XPS): Comparing the N 1s peaks between HA-BP, dodecylamine (C12H25NH2 R−NH2), and methylammonium chloride (CH3NH3Cl, R−NH2) reveals that HA-BP and R−NH2 have the same binding energy, which is blueshifted by 2.4 eV from that of R−NH2 (Fig. 2B). Contact-angle measurements also show that the surface of BP becomes more hydrophobic after HA coating (SI Appendix, Fig. S2), confirming that the HA coating is indeed terminated by alkyl chains, not by amine/ammonium groups.

Inspection by atomic force microscopy (AFM) of the height profile of the same 2D flake before and after coating revealed that the n-hexylamine coating is around 1.5 nm thick (Fig. 2C), which is consistent with the theoretical chain length of n-hexylamine (41). This demonstrates that the deposition of n-hexylamine molecules is self-limiting. Polar organic solvents including acetone, ethanol, or isopropanol, as well as nonpolar solvents like hexane, cannot remove the n-hexylamine coating, indicating that the interaction between n-hexylamine and BP is strong enough to sustain solvent attack. We also note that n-hexane does not impart any corrosion protection, attesting that the amine group is key for this function and that the alkyl chain itself cannot bind strongly on BP.

We employed first-principles calculations to investigate the transport of protons when n-hexylamine approaches P−OH (Fig. 2D), formed by reacting with the water from the n-hexylamine coating solution. Among various structural possibilities after systematic study, with results shown in SI Appendix, Figs. S3–S6, the most likely reaction pathway agrees with the scenario (P−O−NH−H3C−H2) proposed above and yields a bonding energy of 0.97 eV, which is 3 to 4× stronger than the pure vdW interaction [−0.33 eV between n-hexylamine and pure BP, −0.22 eV between amines and graphene (42)]. The electronic density distribution shows that the H atom shares its orbital much more with N atom than with O atom (Fig. 2D, Inset), and Bader charge analysis indicates that n-hexylammonium (C6H13NH3+) carries a net charge of +0.89e, and to compensate, the rest has −0.89e.

In Fig. 2E, the migration energy barrier of H2O penetrating through n-hexylamine is calculated to be 1.4 eV and O2 1.0 eV, when n-hexylamine covers BP in the densest possible packing structure (hereafter defined as 100% coverage, shown in SI Appendix, Figs. S8 and S9); when the coverage drops to 66.7%, the migration energy barrier reduces to 0.2 eV for H2O permeation and no barrier (0 eV) for O2. When the HA coverage further decreases to 50% or 25%, the migration of both H2O and O2 through the HA layer toward the surface of BP is barrierless. Combining this theoretical analysis with the time-evolution XPS data on phosphorus oxide concentration (Fig. 2F and G), where the oxidation speed of phosphorus after n-hexylamine coating is significantly reduced by 32× at the beginning of oxidation (fitting method and definition of time constant can be found in
Fig. 2. The mechanism of n-hexylamine coating on BP. (A) Proton transfer takes place during the coating process (Upper) and the n-hexylamine monolayer is formed on BP after the coating process is done (Lower). R- in the diagram refers to C4H9- when representing hexylamine. (B) XPS spectra of nitrogen 1s peaks on HA-BP, dodecylamine (C-NH2), and CH3NH3Cl (C-NH3+), proving that the amino group of n-hexylamine coated on BP is in ionic state –NH3+. (C) The AFM data revealing the thickness of a BP flake with 24 nm before coating (pink line) and the thickness increment after hexylamine coating (violet line). (D) The schematic structure of n-hexylamine adsorbed on BP, where red-, blue-, gray-, purple-, and white-colored balls represent oxygen, nitrogen, carbon, phosphorus, and hydrogen, respectively. (Inset) the contour map of valence electron density on the plane containing O, N atoms and the H atom between them, which corresponds to the part marked by rectangle dashed line. (E) The energy profile of H2O and O2 molecules when penetrating through the hexylamine molecule layer. The y axis is the distance between the bottom atom of H2O or O2 and the surface of BP, denoted as d. Blue and red curves represent H2O and O2 penetration processes, respectively. The 4 groups of curves represent different coverages of 25, 50, 66.7, and 100% (detailed coverage definition illustrated in SI Appendix, Fig. S7), as marked. The horizontal gray lines are the locations of the top and the bottom of hexylamine molecules. (F) The P 2p peaks and oxidized phosphorus species (R-P-O) of XPS curves on HA-BP measured as coated, after 2 d, and after 46 d. (G) The phosphorus oxide concentration as a function of time between n-hexylamine-coated (violet triangles) and uncoated BP samples (pink squares). (Inset) A blow-up of the uncoated sample data between 0 and 15 h. Both datasets are fitted with exponential curves. The pink and violet solid lines are fittings of the scattered data pointing to the uncoated and HA-coated samples, respectively. Note that the oxidation of HA-BP is a significant slowdown starting from 100 h, so a second curve fitting is marked (dashed violet line). (H) Schematic illustration of the structure of BP after coating by n-hexylamine. The first layer of BP is oxidized and forms a part of protective layer together with the n-hexylamine coating. The surface protective layer (hexylammonium + first-layer oxidized BP) protects the rest of BP underneath.
SI Appendix), we deduce the coverage density of n-hexylamine on BP must be more than the defined 66.7% coverage on the surface of BP.

With these conclusions, a schematic illustration of the molecular monolayer can be shown in Fig. 2H. The top oxidized BP layer of PO, together with the coated n-hexylamine monolayer forms a dense protection layer for the BP underneath. It lowers the penetration speed of O2 molecule significantly and blocks the H2O molecule almost completely under room temperature, thus stabilizing the surface passivation layer (the oxidized BP at the top).

The anticorrosion effect conferred by organic monolayer is not limited to n-hexylamine. Indeed, other linear alkylamines \( n-C_{n}H_{2n+1}NH_{2} \) with \( m = 4 \) through 11, including n-butylamine \( (n-C_{4}H_{9}NH_{2}) \), n-pentylamine \( (n-C_{5}H_{11}NH_{2}) \), n-octylamine \( (n-C_{8}H_{17}NH_{2}) \), n-decylamine \( (n-C_{10}H_{21}NH_{2}) \), and n-undecylamine \( (n-C_{11}H_{23}NH_{2}) \), all consistently displayed similar anticorrosion effects in ambient air. Their coatings onto BP for anticorrosion demonstration are presented in SI Appendix, Table S2, and the growth parameters for coating all these alkylamines with different carbon chain lengths are summarized in SI Appendix, Table S3.

To demonstrate the passivation efficacy for actual optoelectronic devices in ambient and aggressive environments, we fabricated 2 BP-flakes-based photodetectors. As a direct bandgap semiconductor, with its \( E_{g} \) continuously tunable from \( \sim 2 \) eV (single layer) to 0.3 eV (bulk) (43) by varying the number of layers, BP stands out as a promising material for photonic devices from near-infrared to midinfrared. The layout of the uncoated BP detector with a channel length and width of \( \sim 3 \) and \( \sim 5 \) \( \mu \)m, respectively, between the Ti/Au electrodes is shown in Fig. 3A. The thickness of the BP here is 74 nm (SI Appendix, Fig. S10). The \( n \)-hexylamine–coated BP photodetector is shown in Fig. 3B, with comparable channel dimension and a BP thickness of 55 nm (SI Appendix, Fig. S10). Note here, the photocurrent for bare BP device is significantly lower than the protected one due to the fast degradation of BP in air during sample loading and contacting electrical probes. The photocurrent and current density as a function of input optical power under zero voltage bias (Fig. 3A and B, uncoated and coated respectively) was measured in ambient air with a 1,550-nm laser. The coated BP can sustain annealing in \( H_{2} \) environment under 250 °C for 1 h, provided by \( H_{2} \)-curtain oven experiment. Both devices exhibited increased photocurrent with input power before etching (black lines labeled with preetching in these plots). After dipping the devices in \( H_{2}O_{2} \) for 5 s and drying them subsequently, obvious degradation was observed under optical microscope on the uncoated BP device (Fig. 3A, Upper-Right Inset), while little change was found on the coated one (Fig. 3B, Upper-Right Inset). As evidenced by the photoelectric signal, corrosion caused severe damage to the uncoated optoelectronic device, with the photocurrent dropping to 0. In contrast, the \( n \)-hexylamine–coated photodetector device maintained 78.6% of its original photocurrent based on the photocurrent values of 28.7 \( \mu \)A at postetching and 36.5 \( \mu \)A at preetching under photocexcitation with the same input power of 3 mW. The slight drop of performance likely originates from defects in the coating layer within the boundaries between the electrode metal and the BP flake, and also likely originates from the residue of PMMA during the deposition of electrodes that blocks the spreading of hexylamine.

Such monolayer protection is effective not only for BP, but also for other layered 2D materials. Here, to accelerate corrosion tests for \( n \)-hexylamine–coated 2D materials, we used harsh aqueous \( H_{2}O_{2} \) or \( KMnO_{4} \) solutions as etchants. In Table 1, we present the optical microscopy images during the corrosion exposure for each 2D material, including BP, \( WS_{2} \), \( WSe_{2} \), \( 1T’-MoTe_{2} \), \( WTe_{2} \), \( TaS_{2} \), and \( NbSe_{2} \). It should be noted that exfoliated BP, \( 1T’-MoTe_{2} \), \( WTe_{2} \), \( NbSe_{2} \), and chemical vapor deposition (CVD)-grown single-layer \( WS_{2} \) are known to be particularly susceptible to ambient corrosion and are readily attacked by solutions of \( H_{2}O_{2} \). \( WSe_{2} \) and \( TaS_{2} \) are less vulnerable and require stronger oxidants for corrosion. \( n \)-hexylamine is proved to be effective in protecting these layerd materials based on the comparison in optical image between uncoated and coated 2D materials after their exposure to the same etchants. A movie of the corrosion retardation for BP is presented as Movie S1.

Despite the fact that \( n \)-hexylamine is sturdy under various environments, it is still removable by certain organic acids. Presumably, the organic-media–supported protons can penetrate the hydrophobic alkyl layer and protonate the ionized surface \( P-O^- \) groups, disrupting their electrostatic interaction with the alkylammonium cations. This removing protocol is effective both for the amine coating on BP and TMDs, without affecting the passivation oxidized layer and the materials underneath (SI Appendix, section 5).

Discussion

Amines with low water solubility have long been known as efficent and reliable corrosion inhibitors for steels (41, 44). It is found here that they also serve as an effective coating for 2D

BP, WS₂, 1T'-MoTe₂, WTe₂, WSe₂, TaS₂, and NbSe₂ were coated with n-hexylamine and dipped inside etchants of H₂O₂ or KMnO₄ solution (depending on the respective material reactivity) as an accelerated lifetime test. The uncoated counterparts were processed in parallel with the coated parts under identical etching conditions. (Scale bars, 10 µm.)
layered materials, by blocking water for the native-thin oxide layer growing at the interface between the 2D material and the alkylamine coating. The photooxidation of bare BP starts with the synergistic effect of oxygen, water, and light, where phosphorus transformed to a layer of acidic phosphorus species. The thin layer of acid then coarsens into a droplet, leaving a fresh phosphorus surface in contact with ambient air, and the oxidation process starts once again (45). n-hexylamine monolayer lowers the permeability of oxygen and strongly blocks the water molecules from directly contacting the oxide passivation layer and phosphorus. Although the first BP layer is still oxidized by O2, it is isolated from ambient humidity by the hydrophobic alkyl monolayer, which prevents the water from dissolving this top layered materials, by blocking water for the native thin-oxide.

The facile coating method can be implemented onto its surface. General applicability on a variety of other layered materials is also demonstrated. The alkylamine monolayer is robust in a range of chemical and thermal environments, including ambient air. The facile coating method can be implemented with many different substrates and is compatible with all linear alkylamines no shorter than n-butylamine, thus offering a platform for controlling the surface physics and chemistry of a rich tableau of 2D materials. Because of its simplicity, ecofriendliness, and low cost, we envision it to be scalable and adaptable in various industrial configurations.
