ABSTRACT

We present a spatially resolved near-UV/optical study, using the Wide Field Camera 3 (WFC3) on board the Hubble Space Telescope, of NGC 4150, a sub-L∗, early-type galaxy (ETG) of around 6 × 10^9 M⊙, which has been observed as part of the WFC3 Early-Release Science Programme. Previous work indicates that this galaxy has a large reservoir of molecular hydrogen gas, exhibits a kinematically decoupled core (a likely indication of recent merging) and strong, central Hβ absorption (indicative of young stars). While relatively uninspiring in its optical image, the core of NGC 4150 shows ubiquitous near-UV emission and remarkable dusty substructure. Our analysis shows this galaxy to lie in the near-UV green valley, and its pixel-by-pixel photometry exhibits a narrow range of near-UV/optical colors that are similar to those of nearby E+A (post-starburst) galaxies and lie between those of M83 (an actively star-forming spiral) and the local quiescent ETG population. We parameterize the properties of the recent star formation (RSF; age, mass fraction, metallicity, and internal dust content) in the NGC 4150 pixels by comparing the observed near-UV/optical photometry to stellar models. The typical age of the RSF is around 0.9 Gyr, consistent with the similarity of the near-UV colors to post-starburst systems, while the morphological structure of the young component supports the proposed merger scenario. The typical RSF metallicity, representative of the metallicity of the gas fuelling star formation, is ~0.3–0.5 Z⊙. Assuming that this galaxy is a merger and that the gas is sourced mainly from the infalling companion, these metallicities plausibly indicate the gas-phase metallicity (GPM) of the accreted satellite. Comparison to the local mass–GPM relation suggests ( crudely) that the mass of the accreted system is ~3 × 10^8 M⊙, making NGC 4150 a 1:20 minor merger. A summation of the pixel RSF mass fractions indicates that the RSF contributes ~2%–3% of the stellar mass. This work reaffirms our hypothesis that minor mergers play a significant role in the evolution of ETGs at late epochs.

Key words: galaxies: elliptical and lenticular, cD – galaxies: evolution – ultraviolet: galaxies

1. INTRODUCTION

Over recent decades, a central topic in observational astrophysics has been the star formation histories (SFHs) of massive early-type (elliptical and lenticular) galaxies (ETGs). Early types host more than 50% of the stellar mass density in the nearby universe and, given their dominance of the galaxy census, it is important that we develop a thorough understanding of their formation and evolution. The broadband optical colors of massive ETGs are red and show a tight correlation with luminosity; more luminous galaxies possess redder colors. Since early types are not generally dusty, their optical colors imply that the bulk of the stellar population is old (>3 Gyr) and perhaps coeval (e.g., Bower et al. 1992, 1998; Ellis et al. 1997; Stanford et al. 1998; Gladders et al. 1998; van Dokkum

Figure 1. Sensitivity of the UV–optical color of composite stellar populations to young stars. Each composite population assumes two instantaneous bursts of star formation, the first burst fixed at old age/high redshift (z = 3) while the second is free to vary in age and mass fraction. These models also assume solar metallicity and no dust. The NUV–optical color (in this case HST WFC3 F225W − F555W) of the composite stellar population is plotted as a function of the age (symbol) and mass fraction (abscissa) of the second burst. It is clear that even a small mass fraction (~1%) of young stars (~1 Gyr) results in a significant change in the NUV − V color compared to that of a purely old stellar population (F225W − F555W ~ 6.4). The spectrum of the young component begins to dominate the combined SED as its mass fraction increases beyond ~5%. Hence, for higher mass fractions, the UV–optical color remains more or less constant.

to young stars. Each composite population assumes two instantaneous bursts of star formation, the first burst fixed at old age/high redshift (z = 3) while the second is free to vary in age and mass fraction. These models also assume solar metallicity and no dust. The NUV–optical color (in this case HST WFC3 F225W − F555W) of the composite stellar population is plotted as a function of the age (symbol) and mass fraction (abscissa) of the second burst. It is clear that even a small mass fraction (~1%) of young stars (~1 Gyr) results in a significant change in the NUV − V color compared to that of a purely old stellar population (F225W − F555W ~ 6.4). The spectrum of the young component begins to dominate the combined SED as its mass fraction increases beyond ~5%. Hence, for higher mass fractions, the UV–optical color remains more or less constant.

The tight fundamental plane and the high alpha-enhancement ratios (e.g., Worthey et al. 1992; Carollo et al. 1993; Kodama & Arimoto 1997; Trager et al. 2000) further suggest small ranges in the epoch and duration of ETG star formation. However, a significant drawback of optical colors is their insensitivity to moderate amounts of recent star formation (RSF). Indeed, high-precision optical spectroscopy has consistently suggested extended periods of star formation lasting until a few Gyr ago in some ETGs and has recently demonstrated that the luminosity-weighted ages of local ETGs have a large range and correlate with both velocity dispersion and environment (Trager et al. 2000; Nelan et al. 2005; Thomas et al. 2005; 2010; Graves et al. 2009; Scott et al. 2009). The currently accepted Lambda Cold Dark Matter (ΛCDM) paradigm suggests that this behavior is due to gas infall and merger events that continue to recent times (Kaviraj et al. 2005), although some of the cold gas fueling star formation may be produced internally through stellar mass loss (e.g., Sarzi et al. 2006; Young 2005). Recent observational studies (e.g., Kaviraj et al. 2010; Kaviraj 2010) have highlighted the role of minor mergers (progenitor mass ratios <1:4) in the late-epoch (z < 1) evolution of ETGs.

An efficient way to pursue the problem of late star formation in ETGs without the need for high signal-to-noise (S/N) spectroscopy is to employ rest-frame ultraviolet (UV; shortward of 3000 Å) imaging. While their impact on the optical spectrum is weak, small mass fractions (<5%) of young (<0.5 Gyr old) stars can strongly affect the near-UV (2000–3000 Å) (see Figure 1). Following the study by Yi et al. (2005), Kaviraj et al. (2007c) comprehensively studied the UV properties of a large sample (~2100) of massive (M* < 21) ETGs in the nearby universe (0 < z < 0.11), by combining UV data from the Galaxy Evolution Explorer (GALEX) mission (Martin et al. 2005) with optical data from the Sloan Digital Sky Survey (SDSS; Abazajian et al. 2009). When upper limits to the UV flux from evolved stellar stages are considered, e.g., extreme horizontal branch (EHB) stars which drive the “UV-upturn” phenomenon typically observed in giant cluster ellipticals (Yi et al. 1999), 20%−30% of massive ETGs are found to contain unambiguous signatures of RSF, because their UV–optical SEDs cannot be produced by the EHB alone. It is worth noting that since upper limits to the UV flux from old stars are considered, the fraction of “star-forming” ETGs becomes a (robust) lower limit. A more reliable result can be obtained by studying the rest-frame UV properties of ETGs at z > 0.5, where the horizontal branch is not yet in place and the rest-frame UV becomes a more reliable indicator of the presence of young stars. By exploiting deep optical U- and B-band data to trace the rest-frame UV, Kaviraj et al. (2008) have demonstrated that at these redshifts a negligible fraction of ETGs are consistent with purely passive aging since high redshift, supporting the low-redshift GALEX results and suggesting that RSF is a widespread phenomenon in the ETG population over at least the last 8 billion years. The mass fractions forming in the RSF events range from fractions of a percent to a few percent, with luminosity-weighted ages of ~300–500 Myr (Kaviraj et al. 2007c). It is worth noting that the large spread (~5 mag) in the NUV–optical colors cannot be reproduced by RSF driven solely by internal stellar mass loss, pointing to an external origin for the gas that fuels that star formation. This seems consistent with recent work that suggests that the RSF is driven by minor mergers.

The Hubble Space Telescope (HST) program exploited in this study extends and enhances these results by exploring the spatial distribution of young stars in ETGs, which promises crucial insights into the processes that lead to star formation in early-type systems. In this paper, we use high-resolution NUV–optical photometry from the HST Wide Field Camera 3 (WFC3) to accurately quantify the age, metallicity, mass, and spatial distribution of young stars in the ETG NGC 4150, with the aim of constraining the characteristics of the suspected merger event (e.g., age, mass ratio) believed to have triggered the recent starburst.

1.1. The Target Galaxy: NGC 4150

The properties of NGC 4150 are detailed in Table 1. This galaxy was also one of the targets for the SAURON project (Bacon et al. 2001; de Zeeuw et al. 2002). NGC 4150 is characterized as a lenticular (S0) galaxy at z=2000 = 12 10 33:67, β2000 = +30′24′05′59, which shows signs of RSF. Previous observations have shown it to possess blue NUV–optical colors (Jeong et al. 2009), enhanced central Hβ absorption (Kuntschner et al. 2006), large quantities of molecular gas (Combes et al. 2007), and a kinematically decoupled core (Krajnović et al. 2008). The first two characteristics are indicative of RSF. The latter characteristics point toward a past merger with a less massive, gas-rich galaxy as the source of both the gas and the disturbed dynamics in the center of NGC 4150, and as the trigger for the RSF.

Several authors (e.g., Huchra & Geller 1982; Kundu & Whitmore 2001) have associated NGC 4150 with the Canes Venatici I group (also M94 group), the majority of whose member galaxies are within 2−8 Mpc of our Sun, with a median distance of ~4 Mpc (Makarova et al. 1998). However, the distances estimated for NGC 4150 in the literature are somewhat larger than this value. Tonry et al. (2001) calculated a distance modulus, μ = 30.69 ± 0.24 (d ≈ 13 ± 1.5 Mpc) from measurements of I-band surface brightness fluctuations (SBFs), calibrated using Cepheid distances to other nearby
galaxies. Jensen et al. (2003) later updated this value to $\mu = 30.53 \pm 0.24$ after re-calibrating the data using the Cepheid period–luminosity relation of Udalski et al. (1999). Rekola et al. (2005) found this mass are classified as AGNs (Kauffmann et al. 2003).

The mass of molecular hydrogen in NGC 4150 was computed from the mean heliocentric velocity of the Coma I cloud ($\mu = 0.018$ mag) and assuming $H_0 = 75$ km s$^{-1}$. Indeed, de Zeeuw et al. go on to associate NGC 4150 with this group of galaxies, which lies on the outskirts of the Virgo cluster.

We have estimated the stellar mass of NGC 4150, $M_*$, from its $K_s$-band luminosity (Temi et al. 2009) using the stellar mass–light ratios derived by Bell et al. (2003). Bell et al. derived $M/L$ ratios for a large sample of galaxies from the Two Micron All Sky Survey (2MASS) and the SDSS, and compared these with galaxy colors (see Bell et al. 2003, Appendix B). From these $M/L$–color relations, and using the $(B-V)$ color of NGC 4150, we calculated $M_*/L_{K_s} = 0.63^{+0.3}_{-0.2}$, and hence $M_* = 6.3^{+3.1}_{-2.1} \times 10^9 M_\odot$. NGC 4150 is unlikely to harbor an active galactic nucleus (AGN) as just a few (~5) percent of local galaxies of this mass are classified as AGNs (Kaufmann et al. 2003).

The mass of molecular hydrogen in NGC 4150 was computed by Welch & Sage (2003) and Combes et al. (2007) from measurements of CO emission. The two groups derived masses of $M_{\text{H}_2} = 3.8 \times 10^7 M_\odot$ and $6.6 \times 10^7 M_\odot$, respectively, with much of the discrepancy between these two values being due to different CO–to–$\text{H}_2$ conversion factors.

In the following sections, we introduce new $HST$ WFC3 observations of NGC 4150 and compare its integrated NUV–optical photometry with that of the nearby ETG population (Section 2), perform a pixel-by-pixel analysis of the central region of the galaxy, estimating the age, mass, metallicity, and extinction of the young stellar populations (Section 3), and use our results to determine the star formation and assembly history of this nearby lenticular galaxy (Section 4).

### 2. OBSERVATIONS, DATA REDUCTION, AND PRELIMINARY ANALYSIS

Observations of NGC 4150 (see Table 2) were made using the newly installed WFC3 on board the $HST$. The observations formed part of an Early Release Science Program ($HST$ program 11360, PI: Robert O’Connell) led by the WFC3 Scientific Oversight Committee. The main objective of this program is to study star formation in a range of different environments (early-type, quiescent and star-forming galaxies) in the local universe.

All data were downloaded from the $HST$ archive\(^{22}\) at the Space Telescope Science Institute (STScI) via the on-the-fly recalibration pipeline, which implemented the CALWFC3 software to bias, dark, and flat-field correct the images. We further reduced the data locally using the MULTIDRIZZLE software (Koekemoer et al. 2002) to register individual exposures in a given filter, apply distortion corrections, mask out cosmic rays and other defects, and finally combine the exposures using the drizzle image reconstruction technique developed by Fruchter & Hook (2002). The data were drizzled using the latest image distortion coefficient tables (IDCTAB) downloaded from the WFC3 reference file Web site.\(^{23}\)

Figure 2 shows a pseudo-color (RGB) image of NGC 4150 created using the WFC3 $UVIS$ $F814W$, $F555W$, and $F438W$ frames for the red, green, and blue channels, respectively. In this optical image, NGC 4150 appears to be a typical S0 galaxy possessing a dominant bulge, albeit with obvious dust lanes toward its center. The white boxes indicate the fields of view presented in Figure 3, which shows both pseudo-color and monochromatic images of the central region of NGC 4150. The RGB images in this case are a combination of $UVIS$ $F657N$ (H$\alpha$+[N II]—red), $F438W$ (green), and $F225W$ (blue), while the gray-scale images are unsharp-masked versions of the $F438W$ data. Unsharp-masking was performed by first median boxcar smoothing the $F438W$ image using a box of 50×50 pixels, before subtracting the smoothed image from the original. This had the effect of enhancing smaller scale structures, in particular the details of the dust distribution in the center of NGC 4150. Figure 4 shows gray-scale versions of the $UVIS$ observations of the galaxy core through each of the NUV–optical filters.

Two issues are immediately obvious from the images in Figures 3 and 4: (1) the unobscured areas of the core of

(1993) IMF (NGC 4150: $M_*/L_{K_s} = 0.6^{+0.3}_{-0.2}$); (8) molecular hydrogen masses from Welch & Sage (2003) and (9) Combes et al. (2007).
Figure 2. RGB image of local S0 galaxy NGC 4150 created from WFC3 UVIS $F_{438W}$ (blue), $F_{555W}$ (green), and $F_{814W}$ (red) observations. The white squares indicate the fields of view shown in (a) and (c) (large box) and (b) and (d) (small box). North is up and east is to the left.

NGC 4150 are bright in the NUV/$F_{225W}$ (Figure 4(a)), appearing blue in the color composite images (Figures 3(a) and (b)) and (2) there are significant amounts of dust, which forms a spiral-like structure and appears to rotate clockwise (north to west) in the plane of the galaxy disk. Some of this dust lies across the line of sight to the very center and lower part of the galaxy core, blocking our view of this region at shorter wavelengths, as is well illustrated by the sequence of images in Figure 4.

Jeong et al. (2009) also observed NGC 4150 to have a NUV bright core and blue NUV–optical colors, albeit at much lower resolution (NUV PSF ≈ 6″) using the NASA GALEX24 (Galaxy Evolution Explorer) satellite (see Figure 5). UV flux is generally associated with two distinct stellar populations; young ($\lesssim$1 Gyr), massive stars, and old ($\gtrsim$5 Gyr), low-mass, core helium burning (horizontal branch, HB) stars. The latter are believed to be responsible for the UV-upturn phenomenon in which evolved ETGs, devoid of young stars, develop a strong UV-excess (Yi et al. 1997). UV-upturn is typically observed in cluster elliptical galaxies, a signature of an old population (see O’Connell 1999, for a review). Since a UV-upturn requires a galaxy’s stellar population to have aged sufficiently to allow development of a strong EHB, we do not expect to observe this phenomenon in galaxies beyond $z \gtrsim 1.5$, when the universe was less than 5 Gyr old. However, NGC 4150 is effectively at $z = 0$, and hence we must consider that UV-upturn is at least a possibility in this case.

By using the corollary evidence of a central, Hβ absorption “hotspot” of roughly 2″ radius (Kuntschner et al. 2006)—indicative of young (<2 Gyr) stars—and the detection of large quantities of molecular gas (Combes et al. 2007)—the fuel required to form new stars—Jeong et al. (2009) concluded that the NUV flux in NGC 4150 is most likely dominated by young stars created during a recent period of star formation.

Utilizing the exquisite resolution of our HST data set we can add a further, morphological argument. We see in Figure 3(b)

24 http://www.galex.caltech.edu/
and, more clearly, in Figure 4(a) that there is significant structure in the NUV image, owing not only to attenuation by dust, but also to the presence of several bright knots of NUV flux. If the flux was attributable to old, low-mass stars one would expect the NUV image to be much smoother, similar to the optical V (F555W) and I (F814W) images (disregarding dust attenuation) which effectively trace the old stellar population in NGC 4150. These localized knots of NUV flux, which exist only within about 3″ (~200 pc) of the center, point toward a population of younger stars as their source, the clumps of young stars having not yet dispersed since their formation in the recent past.

Figure 6 shows a color–magnitude diagram on which we have plotted the integrated UVIS photometry of NGC 4150 within one effective radius (Reff ~ 400 pixels) compared with the nearby ETG population identified by Kaviraj et al. (2007c) in SDSS DR3 and GALEX MIS data. The blue horizontal line indicates the (NUV – V) color of the strongest UV-upturn galaxy in the local universe, NGC 4552, in which the NUV flux is dominated by HB stars that have evolved from the old, low-mass stellar population. The (NUV – V) color of NGC 4150 is significantly bluer than this empirical UV-upturn limit, adding further support to the argument that it is due to RSF.

It is worth noting that there is a conspicuous lack of Hα emission25 coincident with the NUV knots, or indeed anywhere in the core of NGC 4150 (Figures 4(e) and (f)). The continuum subtracted from the raw F657N image was estimated from an average of the F555W and F814W observations, which was scaled to match the F657N photometry of two K-type stars26 in the field. The lack of Hα emission suggests that there are few, if any, very young stars (~<10 Myr) in the region and that the proposed burst of RSF ended some time ago. The possibility that NGC 4150 is a post-starburst system is a point we return to in the following sections.

25 A bright source of Hα emission is visible just north of the galaxy core in Figure 4(f). This is potentially a young GC, one of a population of such objects in NGC 4150 that will be discussed more fully in a forthcoming paper (S. Kaviraj et al. 2011, in preparation).

26 K-type stars were chosen as they exhibit weak H-absorption lines. Conversely, the A-type star visible to the southeast of the galaxy core in Figures 2 and 3 was rejected as stars of this type possess strong H-absorption features.
3. DETAILED ANALYSIS—PHOTOMETRY AND PARAMETER ESTIMATION

There are several means by which one might attempt to derive the SFH of a target galaxy or stellar population. If the constituent stars are sufficiently resolved it may be possible to perform photometry on each in turn, and subsequently derive individual estimates for age, mass, and metallicity through comparison with stellar models. Coeval populations are trivially identified from such analyses and it is possible to build up a detailed and spatially resolved picture of the SFHs in such cases (e.g., Kaviraj et al. 2007c; Fall et al. 2005). In such cases it is generally assumed that the stars within a given cluster formed at about the same time and from the same cloud of gas, and hence they are modeled as simple stellar populations—coeval populations of stars of uniform metallicity. One can then use the cluster age distribution to make inferences as to the SFH of the host galaxy. We perform such an analysis on the GC population in NGC 4150 in a forthcoming paper (S. Kaviraj et al. 2011, in preparation), the results of which are complementary to those presented here.

An alternative method in cases where individual stars are not resolved is to perform photometry on a pixel-by-pixel basis before fitting stellar population models to each pixel in turn (e.g., Welikala et al. 2008; Jeong et al. 2007; Kassin et al. 2003; Eskridge et al. 2003; Conti et al. 2003). In this way, one can build up a contiguous map of the properties of the stellar population within a target galaxy. It is this method that we employ in the following sections. While integrated photometry can detect the presence of different stellar populations, a pixel-by-pixel approach can also define their spatial distribution within the host galaxy. The structures revealed in these two-dimensional maps provide vital clues as to where and how the constituent stars formed.

3.1. Pixel-by-pixel Photometry

Pixel-by-pixel photometry of the core of NGC 4150 was carried out on the WFC3 UVIS observations taken in five broadband filters; F225W, F336W, F438W, F555W, and F814W. We have concentrated our efforts on the galaxy core since this is where we observe significant levels of NUV flux, which is most likely associated with young stars. NUV photometry is crucial for the accurate determination of stellar ages (see Section 3.2) and hence we limit our analysis to those pixels with NUV (F225W) S/N greater than 5. Small x,y shifts were applied, where necessary, to align each of the drizzled images relative to the F438W frame, before 160×160 pixel square sections of each image were created (6′/4 or 420 pc on each side), centered roughly on the galaxy core. (The image sections displayed in Figure 4 are in fact those used in the following analysis.) The sky background in each image was measured from the median counts in several blank regions of sky to the NE and SW of the galaxy core, and well beyond the extent of its optical disk. These sky background levels were subtracted from each of the WFC3 images prior to calculating the photometry.

The sky-subtracted image sections were read into a custom-built C program which calculated the AB magnitude,27 photometric error, and S/N of each pixel, applying the zeropoints published on the WFC3 Web sites.28 Photometric errors were calculated taking into consideration both the total number of photoelectrons collected by a given pixel over the course of an observation, and the readout noise associated with the UVIS detectors—Equations (1) and (2):

\[
\sigma_X = \sqrt{F_X + R^2} \tag{1}
\]

\[
m_{\text{err}, X} = -2.5 \log \frac{F_X - \sigma_X}{F_X}, \tag{2}
\]

where \(F_X\) is the total number of photoelectrons collected in a given pixel through bandpass \(X\), \(R\) is the detector readout noise (\(UVIS \sim 3e^-\)), \(\sigma_X\) is the 1σ uncertainty in the pixel electron counts as a result of Poisson and readout noise, and \(m_{\text{err}, X}\) is the associated magnitude error. The S/N was also calculated as \(S/N = F_X / \sigma_X\).

The AB magnitude, photometric error, and S/N for each pixel, in each of the five broadband filters, were output to a multi-column text file, while the photometry for each filter was also output in the form of individual FITS images, with S/N thresholds of \(\gtrsim 5\).

Figures 7–9 detail several qualitative analyses of the WFC3 photometry in the core of NGC 4150. Figure 7 shows a map of the (NUV − V) color created by subtracting the F555W photometry FITS image from its F225W counterpart. Pixels with an S/N less than 5 appear white in this map, having been assigned a null value. (In practice, the spatial extent of the useful color map is limited exclusively by the S/N in the NUV (F225W) image. The S/N of the individual pixels in this image drops below 5 at much shorter radial distance from the galaxy center compared to the optical bands.)

Figures 8 and 9, respectively, show a color distribution (NUV − V) and a color–color plot (NUV − V versus B − V) of the core pixels in NGC 4150. In both cases, the NGC 4150 photometry is compared with pixel colors from a star-forming region in M83 (also imaged with WFC3; Chandar et al. 2010; 28 http://www.stsci.edu/hst/wfc3/phot_zp_lbn

\[27\] \(AB_0 = 0; f_x = 5.63 \times 10^{-20} \text{erg s}^{-1} \text{cm}^{-2} \text{Hz}^{-1}\).
plotted in blue), and integrated colors of nearby ETGs (plotted in black; Kaviraj et al. 2007c). Additionally the integrated colors of nearby E+A galaxies—post-starburst, major-merger remnants with high mass fractions of recent (<1 Gyr old) star formation—are shown on the color–color diagram (plotted in green; Kaviraj et al. 2007a).

The central colors of NGC 4150 are consistent with a post-starburst stellar population, falling between the currently star-forming M83 and the old, passively evolving ETGs. This is in good agreement with our previous observation regarding the lack of significant Hα emission in the core of NGC 4150 (Section 2 and Figures 4(e) and (f)), which suggests that there are few, if any, very young stars (\(<10\) Myr) and that the starburst ended some time ago.

Comparison with the integrated colors of E+A galaxies, “bona-fide” post-starburst systems, shows that the central pixels of NGC 4150 are much redder in the B − V (optical) color, while having similar NUV − V color. This can be explained as being due to higher mass fractions of RSF (\(\sim 20\%–60\%\)) in the E+A galaxies (Kaviraj et al. 2007a). As the mass fraction of RSF increases, the NUV–optical colors become dominated by the young stars and therefore change little with further increases in mass fraction (Figure 1). At the same time, the optical colors become steadily bluer as the optical light from the young stars begins to compete with that from the old, underlying stellar population. This comparison therefore points toward a lower mass fraction of recent star formation in NGC 4150 than in E+A systems, and suggests that any merger event that may have triggered this star formation was most likely a minor merger (component mass ratio <1:4).

### 3.2. Parameter Estimation

We estimated the values of parameters governing the SFH of NGC 4150 by comparing its five-band pixel photometry (NUV, U, B, V, I) to a library of synthetic photometry, generated using a large collection of model SFHs, specifically optimized for studying ETGs at low redshift. Our primary aims were to explore the age of the last star formation event at the pixel-by-pixel level, the fractional mass of stars produced by this star formation, and the metallicity of the recently formed stars. As a result of the fitting process we also recovered the extinction for each pixel. In this particular case of NGC 4150, the foreground (Galactic) extinction was small (\(E(B-V) = 0.018\); Schlegel et al. 1998). We therefore chose not to correct the photometry.
for foreground extinction prior to fitting, but rather estimate the total extinction (Galactic + host) using a single extinction law (Calzetti et al. 2000). This approach might not be reasonable if the foreground extinction was larger, as the extinction curves appropriate for the dust in the Milky Way and host galaxy could be quite different. However, the effects of any differences in the extinction curves are mitigated here due to the small value of foreground extinction.

Before describing our model fitting in detail, we must stress the utility of the UV in alleviating many of the degeneracies that affect similar studies; most notably those between age, metallicity, and extinction. When concerned with the properties of young stellar populations (as we are in this study) the UV spectrum is key, as its response to even small mass fractions of young stars is significantly larger than that of the optical spectrum. As demonstrated by Figure 1 young stellar mass fractions of only a few percent can move the NUV—optical color of a galaxy blueward by several magnitudes, away from the red sequence (i.e., a purely old population). The corresponding change in the optical colors is just a few tenths of a magnitude. As a consequence, while the optical colors of ETGs are red with very little scatter, their UV—optical colors show a spread of almost 5 mag (see Figure 4 in Kaviraj et al. 2007c).

Figure 1 shows that the size of this blueward shift in UV—optical color is extremely sensitive to the age of the RSF, and hence more accurate ages can be determined with the inclusion of UV data. As demonstrated in Kaviraj et al. (2007b), the addition of UV to traditional optical photometry can effectively break the age—metallicity degeneracy, which allows us to simultaneously estimate both the age and the metallicity of the young stars with a reasonable degree of accuracy and precision. With regards extinction, the UV—optical (F225W — F555W) color is a factor of four more sensitive to dust than the optical (F555W — F814W) color, which gives us increased leverage in estimating the dust content in the target galaxy.

We note that, while extremely sensitive to age, the UV—optical color is only weakly dependent on the mass fraction of the RSF, particularly at mass fractions greater than 5%. This is because at greater mass fractions the young stellar component begins to dominate the galaxy spectrum, in the optical as well as the UV. The UV—optical color one measures is then, more or less, simply that of the young stars, and increasing the mass fraction further will only slightly affect the measured color. However, the availability of the optical spectrum alleviates some of the mass fraction degeneracy since a population with a very large fraction of young stars will have both blue UV and blue optical colors, while a largely old population with a few young stars will have blue UV colors and red optical colors. The degeneracies between parameters are therefore much less severe with the addition of UV data and this allows us to estimate the age, metallicity, and dust content of the target galaxy pixels with a high degree of accuracy.

As we describe below, our scheme decouples the most recent episode of star formation from that which creates the bulk, underlying population. We choose a parameterization for the model SFHs that both minimizes the number of free parameters and captures the macroscopic elements of the SFH of ETGs in the low-redshift universe.

Since the underlying stellar mass in ETGs forms at high redshift and over short timescales, we model the bulk stellar population using an instantaneous burst at high redshift. We put this first (primary) instantaneous burst at \( z = 3 \). Note that small changes to the age of the old population do not affect the derivation of the properties of the young stars. The leverage in the parameters that determine the properties of the RSF comes exclusively from the UV spectrum to which the old population does not contribute. The metallicity of the underlying stellar population is fixed at \( Z = Z_\odot \), since bulk stellar populations in ETGs are observed to be metal rich (Henry & Worthey 1999). Past experience indicates that employing a metallicity distribution (e.g., Schawinski et al. 2007) does not alter the derived values of RSF parameters compared to employing an old stellar population with a single metallicity (e.g., Kaviraj et al. 2007c).

A large body of recent evidence suggests that the star formation in these systems in the local universe is driven by minor mergers (see Kaviraj et al. 2010; Kaviraj 2010, and references therein). This star formation is bursty and we model the RSF episode using a second instantaneous burst, which is allowed us to vary in age between 0.001 Gyr and the lookback time corresponding to \( z = 3 \), and in mass fraction between 0 and 1. Our parameterization is similar to previous ones used to study elliptical galaxies at low redshifts (e.g., Ferreras & Silk 2000).

To build the library of synthetic photometry, the metallicity of the second instantaneous burst of star formation is allowed to vary in the range 0.04—2.5 \( Z_\odot \), while a value of dust extinction, parameterized by \( E(B - V) \) in the range 0—1.0, is added to the combined model SFH. The dust model employed in this study is the empirical dust prescription of Calzetti et al. (2000). Photometric predictions are generated by combining each model SFH with the chosen metallicity and \( E(B - V) \) values and convolving with the stellar models of Yi et al. (2003) through the WFC3 filters. The uncertainties in the stellar models (which may contribute to offsets from observational data, e.g., Eisenstein et al. 2001; Yi 2003; Maraston et al. 2009) are taken to be 0.05 mag for the optical filters and 0.1 mag for the NUV passband. The model library contains ~750,000 individual models.

The primary free parameters in this analysis are the age \( \tau_2 \), metallicity \( Z_2 \), and mass fraction \( f_2 \) of the second burst (the mass fraction of the primary burst is simply \( 1 - f_2 \)). A secondary parameter of interest is the overall dust properties of the system. In each case, the value of the free parameters is estimated by comparing the photometry of each pixel to every model in the synthetic library, with the likelihood of each model \( \exp(-\chi^2/2) \) calculated using the value of \( \chi^2 \), computed in the standard way. From the joint probability distribution, each parameter is marginalized to extract its one-dimensional probability density function (PDF). We take the median of this PDF as the best estimate of the parameter in question and the 16 and 84 percentile values as the “1σ” uncertainties on this estimate. In the analysis that follows we present these median parameter values and 1σ uncertainties.

Note that the quality of the \( \tau_2 \) fits depends critically on our access to the rest-frame UV, which hosts most of the flux from hot, young main-sequence stars. The leverage in \( \tau_2 \) comes entirely from the UV/optical colors. Adding more long-wavelength (e.g., WFC3 IR) filters has no impact on the estimation of RSF parameters. Prior experience with 2MASS and UKIDSS NIR data indicates that addition of NIR filters makes the PDFs broader, but does not change the median values of the parameters themselves. Muzzin et al. (2009) also found that inclusion of NIR data had little or no effect on mean parameter values.
4. RESULTS AND DISCUSSION

Figures 10 and 11 show the results from our parameter fitting procedure in the form of both histogram plots of the one-dimensional distributions of the median parameter values within pixels and as two-dimensional parameter maps. In each case, the plots represent the parameters of the second and most recent burst of star formation in a given pixel, while the underlying population is assumed to have formed at high redshift ($z = 3$) and be of solar metallicity (see Section 3.2). Below we discuss the results for each of the parameters (age, metallicity, extinction, and mass fraction) in turn, and offer our interpretation in the context of the star formation and merger history of NGC 4150.

4.1. Age

Figures 10(a) and (b), respectively, show the one-dimensional distribution and the two-dimensional map of the age of the most recent burst of star formation in the central pixels of NGC 4150.
The age histogram reveals a narrow peak in the RSF age around 0.9 Gyr\(^{29}\)(1\(\sigma\) uncertainty of \(\pm 0.12\) Gyr), confirming NGC 4150 to be a post-starburst system as was qualitatively suggested by the lack of \(H\alpha\) emission (Figure 4) and the similarity of NUV–optical colors of the central pixels to those of E+A galaxies (Figure 7). We further interpret this age as that of an assumed merger event which we believe both supplied raw material to, and triggered, the recent starburst.

The RSF age map reveals further details. The vast majority of pixels, as we know from the one-dimensional histogram plot, have an age of 0.8–1.0 Gyr, which are plotted as light blue/turquoise on the two-dimensional map. This Gyr old population forms a broad, spiral-like structure which appears to sweep clockwise from the SE (bottom left) around to the north and finally into the core of the galaxy. It is possible that this population actually forms a ring around the galaxy core, the southern part of which is hidden by dust. However, superimposed on the broad Gyr old population is a narrow, clumpy stream of young stars ranging from \(~500\) Myr (dark blue) to \(~50\) Myr (purple), which spirals from the NE (top left) clockwise into the galaxy core. The age of the RSF varies along this stream, becoming younger as it approaches the core, while the entire feature appears to rotate in the same direction as the dust visible in the unsharp-masked F438W-band image. The clumps (\(~5–10\) pc diameter) appear to be large clusters of young stars. It is possible that the 1 Gyr old population formed in a similar way, the clusters having since dissolved to form the more diffuse structure we see today.

4.2. Metallicity

The median pixel values and spatial distribution of the metallicity of the young stars are shown in Figures 10(c) and (d). The metallicity distribution shows a peak at sub-solar metallicity, with a median value of \(\sim 0.5\) Z\(_{\odot}\) and is truncated at 0.3 Z\(_{\odot}\) (1\(\sigma\) uncertainty of \(\pm 0.13\) Z\(_{\odot}\)). Note that our model library included metallicities as low as 0.04 Z\(_{\odot}\).

From the two-dimensional metallicity map there is a clear evidence for an increase in metallicity toward the center of the galaxy, with values in the central region (yellow to red) ranging from roughly 1.0 to 1.7 Z\(_{\odot}\). Along the clumpy stream of young stars mentioned in Section 4.1, we see an increase in metallicity with decreasing age, with some of the highest metallicities measured being associated with the very youngest populations of stars (\(~30–100\) Myr, purple in age map). However, some pixels on the southern edge of the very young (purple) feature near the center of the age map have metallicities of between 0.3 and 0.7 Z\(_{\odot}\). Indeed the youngest “pixel,” with an RSF age of just 4 Myr, has a metallicity of 0.29 Z\(_{\odot}\).

The Gyr old population (light blue/turquoise in age map) which forms the broad, perhaps spiral, structure we described in the previous section is of sub-solar metallicity, in the range of 0.3–0.7 Z\(_{\odot}\). However, there appears to be a distinct population of 0.8–1.0 Gyr stars, either side of the dust-obscured core, with greater than solar metallicity (orange/red pixels either side of core in metallicity map, which appear light blue/turquoise in age map). Note that the difference in metallicity between these populations (0.3–0.7 Z\(_{\odot}\) and 1.2–1.7 Z\(_{\odot}\)) is significant when compared to the typical 1\(\sigma\) uncertainty of \(\pm 0.13\) Z\(_{\odot}\). In Figure 12, we present, separately, marginalized PDFs for pixels which have young stars with (median) metallicities less than 0.4 Z\(_{\odot}\) and young stars with (median) metallicities between 1 and 1.5 Z\(_{\odot}\), respectively. It is clear from these plots that the low- and high-metallicity populations are indeed distinct. This clear separation is made possible due to the smaller degeneracies between parameters which result from the inclusion of the UV data (see Section 3.2). These two populations clearly formed at around the same time, but must have formed from two distinct sources of gas with different metallicities. We propose that the broad, low-metallicity population formed from material accreted from a gas-rich satellite galaxy during a recent merger interaction, while the higher-metallicity, central population may have formed from metal-rich gas already present in NGC 4150, which, due to gravitational torques induced by the merger interaction, was caused to lose angular momentum and fall to the galaxy center.

Assuming that our hypothesis is correct, the truncated peak in the metallicity distribution (Figure 10(c)) is then representative of the gas-phase metallicity (GPM) of the galaxy that merged with NGC 4150 roughly 1 Gyr ago. From the mass–metallicity relation of Tremonti et al. (2004) we estimate the mass of the accreted galaxy to be \(~3 \times 10^8\) M\(_{\odot}\), roughly 1/20 the mass of NGC 4150 and consistent with a minor merger. This is admittedly a very crude estimate. The extrapolated 1\(\sigma\)

---

\(^{29}\) To check the consistency of our technique, in Figure 10 we compare the NGC 4150 pixel age distribution with that of a currently star-forming region in M83. As one would expect we see a clear peak close to zero for the M83 distribution.
3. Extinction

Figures 10(e) and (f) show the distribution and map of extinction values for each of our fitted pixels. Note that the pixel-by-pixel photometry was not corrected for small Galactic extinction ($E(B-V) = 0.018$; Schlegel et al. 1998) prior to running the parameter estimation (see Section 3.2). The typical $1\sigma$ uncertainty on the fitted values of $E(B-V)$ is $0.035$.

The most obvious (and again reassuring) observation from the extinction map is that it tends to trace the dust, with higher levels of extinction being associated with the dustier regions observed in Figures 3 and 4. The highest levels of extinction ($E(B-V) \sim 0.6-0.8$) are associated with the most recently formed stars (30-100 Myr), which are found in the very core of the galaxy (purple in age map). However, we note that the central population of Gyr old stars, with super-solar metallicities, suffers significantly lower levels of extinction ($E(B-V) \sim 0.1-0.3$).

4.4. Mass Fraction

Figure 11 shows the mass distribution and map. Note that the mass fraction uncertainties are typically larger because the same UV color may be consistent with a wide range of mass fractions. This is essentially because as the mass fraction increases the young stellar component begins to dominate the SED, so that the normalization changes but the shape of the SED (which determines the colors) does not. While the UV color changes rapidly with age (regardless of the mass fraction) the mass fraction itself is more degenerate (Figure 1). Typically the mass fraction errors are much better constrained for low values of mass fractions, which correspond to younger ages ($f_{\text{2,ext}} = \pm 0.04$ for $f_2 < 0.2$; $f_{\text{2,ext}} = \pm 0.1$ for $f_2 > 0.2$).

Weighting the pixel mass fractions by their uncertainties yields a typical of RSF mass fraction of around 20% pixel$^{-1}$. We find that approximately 12% of V-band galaxy light is contained within the fitted pixels in the core of NGC 4150, which further suggests (assuming a constant mass-to-light ratio for the entire galaxy) that roughly 12% of the galaxy mass is contained within these pixels. We therefore estimate the total mass fraction of young stars in this galaxy to be around 2%–3%.

Note that the typical values for the age (1 Gyr) and mass fraction (20%) of young stars in the central pixels of NGC 4150 implies that the young stellar component contributes around 94% of the flux in $F225W$ (NUV), and 64% of the flux in $F555W$ (V) across the fitted region.

5. CONCLUSIONS

We have presented a spatially resolved NUV–optical study of the early-type (S0) galaxy NGC 4150, using new HST WFC3 data. Previous work by other authors has shown this galaxy to have a stellar mass of around $6 \times 10^9 M_\odot$, roughly $5 \times 10^7 M_\odot$ of molecular hydrogen, a kinematically decoupled core (indicative of recent merging), and strong, central Hβ absorption (indicative of young stars). While relatively unimpressive in its optical image (Figure 2), the core of NGC 4150 shows ubiquitous NUV emission and remarkable dusty substructure (Figures 3 and 4). The galaxy lies in the UV green valley (Figure 6) and its pixels exhibit a narrow range of (NUV – V) colors that are similar to those of nearby post-starburst (E+A) galaxies, and lie between those of M83 (an actively star-forming spiral) and the local quiescent ETG population (Figure 7).
We have parameterized the properties of the RSF (age, mass fraction, metallicity, and internal dust content; Figures 10 and 11) in the NGC 4150 pixels by comparing the observed NUV–optical photometry in five filters (F225W, F336W, F438W, F555W, F814W) to stellar models. The typical age of the RSF is around 0.9 Gyr, consistent with the similarity of the NUV–optical colors to post-starburst systems. The RSF age map reveals somewhat younger (∼50–500 Myr) substructure, including a clumpy stream of stars spiraling into the galaxy core.

We found the typical RSF metallicity—which is representative of the metallicity of the gas fuelling star formation—to be ∼0.3–0.5 Z⊙, but note that within 0.75 of the galaxy center the recently formed stars have metallicities in the range 1.0–1.7 Z⊙. We propose that the most central RSF may have been fuelled by metal-rich gas already present in NGC 4150 that was caused to fall into the galaxy center as a result of the merger, while the surrounding stellar population formed from metal-poor gas accreted during the merger. Assuming this scenario to be correct, the lowest RSF metallicities (0.3–0.5 Z⊙) plausibly indicate the GPM of the accreted galaxy. Comparison to the local mass–GPM relation (Tremonti et al. 2004) suggests that was caused to fall into the galaxy center as a result of the merger and that the recently formed stars have metallicities in the range 0.3–0.5 Z⊙ to the local mass–GPM relation (Tremonti et al. 2004) suggests that the mass of the accreted system is crudely that the mass of the accreted system is 10^8 M⊙, making NGC 4150 a 1:20 minor merger. Summing the error-weighted mass fractions of RSF in each of the pixels, we found that the RSF contributes approximately 2%–3% of the total stellar mass of the galaxy.

This work reaffirms our hypothesis that minor mergers play a significant role in the evolution of ETGs at late epochs (e.g., see recent papers by Kaviraj et al. 2010; López-Sanjuan et al. 2010). While many previous works have relied upon integrated photometry of large samples of ETGs, this WFC3 study confirms the value of two-dimensional analyses of individual, nearby systems in which the structure and morphology of the constituent stellar populations can be resolved. In a forthcoming paper (S. Kaviraj et al. 2011, in preparation) we will present a study of the GC population in NGC 4150 using our WFC3 data, while future HST observations will lead to similar investigations of several other nearby, ETGs.
