ABSTRACT

We analyse the kinematics of disc stars observed by the RAAdial Velocity Experiment (RAVE) survey in and beyond the solar neighbourhood. We detect significant overdensities in the velocity distributions using a technique based on the wavelet transform. We find that the main local kinematic groups are large-scale features, surviving at least up to \( \sim 1 \) kpc from the Sun in the direction of antirotation, and also at \( \sim 700 \) pc below the Galactic plane. We also find that for regions located at different radii than the Sun, the known groups appear shifted in the \( v_R-v_{\phi} \) velocity plane. For example, the Hercules group has a larger azimuthal velocity for regions inside the solar circle and a lower value outside. We have also discovered a new group at \( (U, V) = (92, -22) \) km s\(^{-1}\) in the solar neighbourhood and confirmed the significance of other previously found groups. Some of these trends detected for the first time are consistent with dynamical models of the effects of the bar and the spiral arms. More modelling is required to definitively characterize the non-axisymmetric components of our Galaxy using these groups.

Key words: Galaxy: evolution – Galaxy: kinematics and dynamics – solar neighbourhood – Galaxy: structure.

1 INTRODUCTION

The presence of kinematic structures in the velocity distribution of the solar neighbourhood has been well established through the analysis of Hipparcos and other surveys (Dehnen 1998; Famaey et al. 2005; Antoja et al. 2008, hereafter A08). Some of the structures may be related to orbital effects of the bar (Dehnen 2000), spiral arms (Antoja et al. 2011, hereafter A11) or both (Antoja et al. 2009; A11; Quillen et al. 2011). Thus, they can provide constraints on the properties of the non-axisymmetries of the Milky Way (MW) disc. However, the origin of each structure is not yet clear. Some of them could be remnants of disrupted disc stellar clusters or could be associated with accretion events (see review in Antoja et al. 2010).

The RAAdial Velocity Experiment (RAVE; Steinmetz et al. 2006) spectroscopic survey provides the means for a giant leap forwards in the understanding of the origin of the kinematic groups, allowing us to answer primary questions such as: What are the significant groups in the solar volume? Are they local features? Do they change when we move far from the Sun? The RAVE solar neighbourhood sample contains already more stars than any previously available kinematic
data set, such as the Geneva–Copenhagen survey (GCS; Holmberg, Nordström & Andersen 2009). But more importantly, the volume sampled by RAVE is much larger, giving kinematics representative of distant regions of the thin and thick discs. In this Letter, we use the RAVE data to revisit the kinematic groups in the solar neighbourhood and trace them, for the first time, far from the Sun.

2 THE RAVE DATA AND METHODS

RAVE is a magnitude limited multifibre spectroscopic survey in the range of $9 < I < 13$ using the 1.2-m UK Schmidt Telescope of the Anglo-Australian Observatory (AAO). We use here internal data from Burnett et al. (2011), who derived distances for stars in the second and third data releases (Zwitter et al. 2008; Siebert et al. 2011b). Following Burnett et al. (2011), we increase the distances by 10 per cent for hot dwarfs and decrease them by the same factor for giants. The data set includes also proper motions mainly from PPMX (Röser et al. 2008) and UCAC2 (Zacharias et al. 2004), making a sample of 202 843 stars with 6D phase-space information.

The spatial distribution of the sample is shown in Fig. 1 (black points). We use the Galactic Cartesian coordinate system with the Sun at $X = -7.8\,\text{kpc}$, $Y = 0\,\text{kpc}$ (second model in table 2 of McMillan & Binney 2010) and $Z = 0.014\,\text{kpc}$ (Binney, Gerhard & Spergel 1997). The spatial distribution can be explained by the fact that RAVE is a Southern hemisphere survey ($\delta < 2^\circ$). The cone through negative $Y$ is due to the additional colour cut $J - K > 0.5$ that was applied for latitudes $|b| < 25^\circ$ and longitudes $230^\circ < l < 315^\circ$ to select giant stars and probe larger distances in the disc. There are 112 808 stars with $|Z| \leq 300\,\text{pc}$ (grey points). As a comparison, throughout the Letter we will use the GCS sample (hereafter GCSIII) taken from Holmberg et al. (2009). The main differences between the two data sets are that RAVE is a Southern hemisphere survey whereas GCSIII covers the whole sky, that it is much fainter and that it is not restricted to F and G dwarfs. We plot the GCSIII with orange points in Fig. 1. The volume sampled by the RAVE stars is much larger and the kinematics of the thin disc can be now traced beyond $\sim 1\,\text{kpc}$ in the direction of antirotation.

Figure 1. Spatial distribution in $XY$ and $XZ$ of RAVE data with 6D phase-space coordinates (black points). Grey points are stars with $|Z| \leq 300\,\text{pc}$. Orange points are stars in the GCSIII. Other colours are the RAVE subsamples defined in the text. The black dashed line shows the solar circle.
the 3 \sigma and 2 \sigma significance levels in the Gaussian case, respectively. Note that the computation of the significance refers to that of the wavelet coefficients and takes into account the particular distribution of stars (and not only their number) in the structures, and hence it is not directly comparable with the one obtained by counting stars. Nevertheless, in various tests we have performed, we found that the two significances are similar. Tests with randomized data show that by chance one finds 8 per cent of the maxima with a 2 \sigma significance, while 2 per cent reach a 3 \sigma significance level. To perform the calculations we use the stw software developed by CEA (Saclay, France) and Nice Observatory. An estimate of the number of stars in each group is obtained by counting stars enclosed in a circle with the radius of the minimum scale of the considered range of scales.

3 REVISITED SOLAR VOLUME KINEMATICS

Fig. 2(a) shows the velocities of stars in the LS. We use a heliocentric system U, V and W, with the U towards the Galactic Centre. We focus only on the U and V components as the moving groups, except the very young ones (Chereul et al. 1999), have almost indistinguishable mean W (Dehnen 1998; Seabroke & Gilmore 2007). Fig. 2(b) corresponds to the positive WT coefficients (overdensities) in the LS velocity distribution at scales of 6–13 km s\(^{-1}\) (where 6 and 13 km s\(^{-1}\) are the scales of the smoothing filters used in the computation of the WT). This distribution is dominated by clear overdensities. Some structures are elongated in V and slightly tilted. We find nine peaks inside the 3 \sigma confidence level region (marked in red) and 10 more that are 2 \sigma significant (orange). The peaks are numbered from maximum to minimum WT coefficient and are listed in Table 2. Fig. 2(c) shows the same WT for the GCSIII. We thus find similar significant groups in the two independent samples. But in comparison to previous work (e.g. Famaey et al. 2005; A08), with RAVE we have better statistics.

The four main groups that we find in the LS (from 1 to 4) are the well-known Coma Berenices, Hyades, Sirius and Pleiades. These groups were also observed in the RAVE sample by Hahn, Sellwood & Pryor (2011). Their positions agree well with the GCSIII (separation between maxima <10 km s\(^{-1}\)). The only exception is the Hyades stream: the stars of the Hyades open cluster in the GCSIII at (U, V) = (−43, −18) km s\(^{-1}\) (absent in the LS) shift the peak to more negative U. The different ranking of these four groups in the LS and GCSIII may be due to differences in the populations of the samples.

Table 2. Kinematic groups detected in the local sample (LS) at scales of 6–13 km s\(^{-1}\). The columns give order in WT coefficient, name of the group in previous literature (if any), U velocity of the peak, error in the mean U of the stars in the group, V velocity, error in the mean V, approximate number of stars and statistical significance. The last three columns show the equivalent groups for the GCSIII. Velocities are in km s\(^{-1}\).

The Hercules structure is the elongated feature in the U direction at V = −50 km s\(^{-1}\). In the LS, group 6 is its main overdensity. Also groups 8, 10 and 13 (this with higher significance than for the GCSIII) could be associated with it. Note that the detection of localized maxima in elongated and extended structures such as Hercules may be a bias due to the isotropy of the WT. The red dotted contours between the main four groups and the Hercules structure correspond to a 3 \sigma significant underdensity of stars (negative WT coefficients). Another remarkable 3 \sigma underdensity is the so-called edge line (Skuljan, Hearmount & Cottrell 1999) in the upper part of the distribution which is present both in the LS and the GCSIII.

The fifth group in order of WT coefficient (before the Hercules stream) is close to the classic group Wolf 630 studied in Eggen (1971). Group 7 is linked to this group in a branch-like shape (hereafter Wolf elongation). We also find other groups that can be associated with the ones studied by Eggen (1971, 1996). For
instance, group 10 is similar to εIndi, group 9 and 11 are close to γLeo and group 14 could be identified with ηCep.

Group 12 is a new 3σ significant group at \((U, V) = (92, -22) \text{ km s}^{-1}\). It is accompanied by group 18 but only at 2σ level. It has around 50 stars but its location in an empty region of the distribution makes it conspicuous. Note that this is a group on a highly eccentric orbit, moving towards the Galactic Centre at \(\sim 100 \text{ km s}^{-1}\). There are other groups (15–19) yet to be confirmed as they are only 2σ significant. Some of them could be tentatively related to other known groups. For instance, groups 14, 17 or 19 could be related to Arcturus at \(V \sim -110 \text{ km s}^{-1}\) (Eggen 1996). We leave a more thorough comparison to groups in other studies (e.g. Klement et al. 2011; Williams et al. 2011) for future work.

### 4 STRUCTURES BEYOND THE LOCAL VOLUME

The first three panels of Fig. 3 show the velocity structures of the subsamples \(S_{\text{out}}\), \(S_{\odot}\), and \(S_{\text{in}}\). Now we use a Galactic cylindrical coordinate system, \(v_R\) and \(v_\phi\), which is more suitable for distant regions. We use local standard of rest (LSR) circular velocity of \(v_0 = 247 \text{ km s}^{-1}\) and solar movement with respect to the LSR of \((U_0, V_0) = (10.0, 11.0) \text{ km s}^{-1}\) (second model in table 2 of McMillan & Binney 2010). For convenience, we take \(v_0\) and \(v_\phi\) to be positive towards the Galactic Centre and towards rotation (clockwise), respectively, to get the same orientation as \(U - V\). Larger WT scales (11–22 km s\(^{-1}\)) are considered now due to the larger velocity errors in these subsamples (Table 1). We find that for \(S_{\odot}\) and \(S_{\text{out}}\) the general shape of the distribution is preserved and some groups show a relative configuration similar to the LS. Although we show here only three distant regions, the evolution in the location and intensity of the main peaks as one moves away from the LS to these volumes is found to be smooth and continuous. For example, the most populated group in \(S_{\odot}\) (group 1 in the second panel) is the Pleiades group. Also groups 2 and 3 are in the Sirius and Hyades kinematic positions, respectively. Group 4 is the Hercules stream and group 5 corresponds to γLeo. We also see the Wolf elongation, but with no associated maxima. Similar identifications can be done for \(S_{\text{in}}\). By contrast, the velocity distribution in \(S_{\text{in}}\) looks quite different to the LS, its overall shape being elongated with a positive slope in the \(v_\phi\) direction. There are several central groups but they are distributed along the general elongated structure and do not show the same relative configuration as for LS, \(S_{\odot}\) and \(S_{\text{out}}\).

We also find that some groups change their location on the velocity plane in distant regions. The yellow squares in Fig. 3 indicate the cylindrical velocities of the LS groups. For instance, Hercules (group 4) in \(S_{\odot}\) is at the same cylindrical velocity as locally (peak inside the square), but in \(S_{\text{out}}\) it has moved to lower \(v_\phi\). We see that this transition is continuously traced when we consider samples in small steps advancing from \(S_{\text{out}}\) to \(S_{\odot}\), and progressively to inner Galacocentric radius. For \(S_{\text{in}}\), Hercules does not appear as a group separated from the central structures. The \(v_\phi\) of the Wolf elongation follows a similar behaviour with radius. We also observe that some groups move in \(v_R\). For instance, Sirius (group 2) shifts to the right of its corresponding square (the one at the highest \(V\)) for \(S_{\text{out}}\).

The arrows in the upper left of each plot show the median directions of the radial (\(v_{\text{los}}\)) and transverse (\(v_\phi\)) velocity. For these regions, as the radial velocity errors are small (\(\epsilon_{\text{los}} \sim 2 \text{ km s}^{-1}\)), the errors affect mainly the transverse motion (\(\epsilon_\phi \sim 17 \text{ km s}^{-1}\)), distorting the groups in that direction. For the case of \(S_{\text{out}}\), the velocity errors or distance biases would never move Hercules in the observed way. By contrast, for \(S_{\text{in}}\), a distance underestimation could shift Hercules closer to the centre of the distribution. However, as shown in Burnett et al. (2011), distances for giants may have a slight bias but in the opposite direction.

We have evaluated the effects of neglecting the extinction in deriving distances for stars in these regions. By using the dust maps of Schlegel, Finkbeiner & Davis (1998), we find an upper limit on the extinction in the \(J\) band of 0.2 mag (by considering extinction at infinity) for the three subsamples, which would introduce a distance error <10 per cent, which is small compared to the 28 per cent uncertainty due to the distance derivation method itself. We can also test that our results do not depend on the distance method by using only red clump stars. We select these by \(J - K\) colour and gravity using the criteria in Siebert et al. (2011a) and re-derive the distance from their \(J\) or \(K\) magnitude assuming absolute magnitudes \(M_J = -0.87\) and \(M_K = -1.55\) (Zwitter et al. 2008). This gives us subsamples with 30–40 per cent of the initial number of stars. Considering a dispersion of 20 per cent in the absolute magnitude for this population, we find that the transverse velocity errors are reduced substantially, from \(\epsilon_{\phi} \sim 17 \text{ km s}^{-1}\) to \(\epsilon_{\phi} \sim 11 \text{ km s}^{-1}\). Nonetheless, with smaller velocity errors and alternative distances, our results do not change.

We perform another test to establish if errors only could explain the differences in the distant velocity distributions. We study if these velocity distributions could belong to the same parent distribution as the LS, given the velocity errors. To do this, we incorporate the observational errors of \(S_{\odot}\), \(S_{\text{in}}\) and \(S_{\text{out}}\) in the LS velocity distribution. In practice, we use the proper motions and radial velocities of the LS but the distances and sky positions of the distant subsamples to generate 5000 simulated velocity distributions after error convolution. Then we compare the mock distributions with the original one (at \(S_{\text{in}}\), \(S_{\text{out}}\) or \(S_{\odot}\)), by computing the distribution of the Kolmogorov–Smirnov (KS) 2D statistic. Instead of using this statistic directly, as a reference we also compute the distribution of the KS statistic between the mock subsamples in a given location.
themselves. The area of overlap of the two KS distributions (obtained for the mock-original and for the mock–mock comparisons) thus gives us the probability that the distant velocity distributions belong to the same parent distribution as the LS, given the velocity errors. Note that our mock samples may have too large errors because first, the distance errors may be overestimated (Burnett et al. 2011), and secondly, the LS velocities have already their own error. We find that for the three subsamples, this probability is <0.06 per cent. Repeating the same test but introducing also a distance bias of ±10, 20 and 50 per cent does not increase the probability. Only for SN, we find a 5 per cent probability of consistency with the LS, given the velocity errors, if the distances were overestimated by 10 or 20 per cent. But in this case, this bias would move Hercules far from the centre of the velocity distribution, contrary to what we see.

Fig. 3 (right-hand panel) shows the velocity distribution of the subsample Z57 (median height below the plane of Z = −0.6 kpc). Again, some of the LS groups can still be recognized and are 3σ significant. For instance, Hercules is here group 2, the Wolf elongation is present and group 3 has the same velocity as γLeo. For a sample in the same cylinder as Z57 but with heights in the range of −800 ≤ Z ≤ −600 pc (median of Z = −0.7 kpc) Hercules and the equivalent to γLeo are still detected but with 2σ confidence.

5 SUMMARY AND DISCUSSION

We have analysed, for the first time, the velocity distributions in regions that are ∼1 kpc far from the Sun using RAVE data and a structure detection technique based on the WT. We have found that most of the main local kinematic groups (Hyades–Pleiades, Sirius, Hercules, Wolf elongation, γLeo) can be still detected at ∼1 kpc from the Sun in the direction of antitrotation. Some of them also persist at 700 pc below the Galactic plane. Therefore, these groups are actually large-scale features. Given also the spread in age and metallicity of some of these groups (A08), this supports a dynamical origin instead of being dispersed clusters.

In the distant disc volume at the solar circle the groups appear approximately at the same cylindrical velocities as locally. In contrast, for the distant regions (in the direction of antitrotation) at different Galactocentric radii (±600 pc) the groups appear shifted in the velocity plane. These are the first significant changes in the kinematic structures observed in distant disc velocity distributions. Especially at inner radii the relative configuration between the groups changes considerably. These trends are consistent with the typical spatial scale of variation of the kinematic structures in models of e.g. spiral arm effects (A11).

In particular, we show that the Hercules group moves to larger (respectively, smaller) azimuthal velocity at inner (respectively, outer) Galactocentric radius, while it appears at the same velocity at the solar radius. This is the behaviour expected for this structure if caused by the bar’s outer Lindblad resonance (fig. 4 in Dehnen 2000), although it can be also explained based on the epicycle theory for a resonant feature (Quillen et al. 2011). We also observe shifts in Galactocentric radial velocity, which is also observed in several models (Minchev et al. 2010; A11; Quillen et al. 2011).

We have also found a new significant group in the solar neighbourhood and confirmed the presence of structures that were not significant in other studies and samples. Some of the observed features such as the Wolf elongation are generally only vaguely considered in the modelling. These and especially the observed groups in distant regions may constitute the keys for the understanding of the complex kinematics of the MW disc. In particular, the magnitude and direction of the velocity shifts detected here in distant regions may tell us about the specific mechanism that produces them (bar or spiral arm related). Quantitative comparison with the models could allow us to constrain the properties of the spiral arms and the bar of the MW, breaking the degeneracy found when fitting the models only to the main local groups.
